INTRODUCTION

The minerals industry is by far the largest single contributor to the valuation of the State of Wyoming. 1984 valuation on minerals produced in 1983 was $5,577,786,192. This is 70% of the state's total valuation and places Wyoming among the top ten mineral producing states in the nation.

This report outlines the distribution and status of the minerals industry in Wyoming during 1983. The primary mineral commodities produced in the state are reviewed individually and a section on historical mineral production is included in the Yearbook. This section enumerates yearly production figures for the state's primary mineral commodities: bentonite, coal, iron ore, natural gas, petroleum, trona, and uranium from their first commercial development to 1983. The production projections for the next five years give an indication of growth or decline of a particular mineral commodity in both the state and individual counties. Estimates beyond five years are not made because of increasing difficulty in making accurate predictions due to changing economic factors, governmental regulation, decreasing reserves and international developments.

The narrative sections present an overview of the minerals produced in the state and the status of the mineral industry in each county.

The reader desiring more detailed information on the location of various projects or resources is referred to the Oil and Gas Map of Wyoming and the Mines and Minerals Map of Wyoming, available from the Geological Survey of Wyoming and the DEPAD Mineral Development Monitoring System.

Pie charts for county mineral valuation were prepared for those counties where minerals accounted for a least 25% of the total assessed valuation.

Production figures in this Yearbook are net or taxable figures and do not include federal or state royalty production because it is not included in the

assessed valuation. The difference between gross production varies from commodity to commodity because of the changes in percentage of government royalties and the variation on how much is produced from government leases and from private leases. The gross production and the taxable production are as follows:

	Oil (bbls)	Natural Gas (mcf)	Coal (tons)	Uranium (tons)
Gross Production	120,979,721*	539,774,090*	112,043,967	3,219,083
Net Production	110,420,981	395,656,547	107,902,764	3,022,650

	Iron Ore (tons)	Bentonite (tons)	Trona (tons)	Gypsum (tons)
Gross Production	2,478,371	2,196,903	11,509,940	327,642
Net Production	2,478,371	2,183,865	10,542,417	327,642

Appreciation is extended to the mineral companies of Wyoming for their assistance and cooperation in providing estimates of production during the next five years. Also, help and information provided by Lee Wooderson and Jim Felton of the Ad Valorem Tax Division of the State Department of Revenue and Taxation proved invaluable. Special thanks are extended to Gary Glass and his staff of the Geological Survey of Wyoming for assistance in estimating future production levels. Also, much valuable data was supplied by Don Basko of the Wyoming Oil and Gas Conversation Commission.

Any questions or comments may be addressed to:

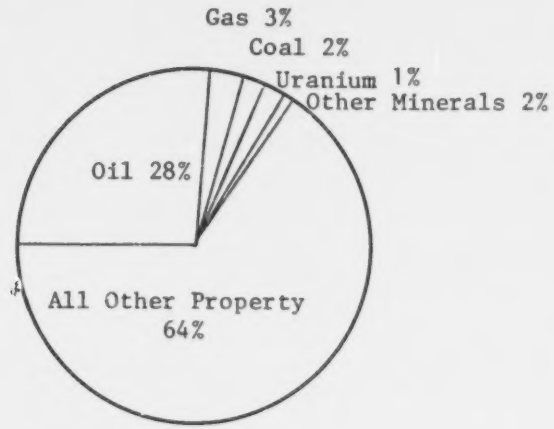
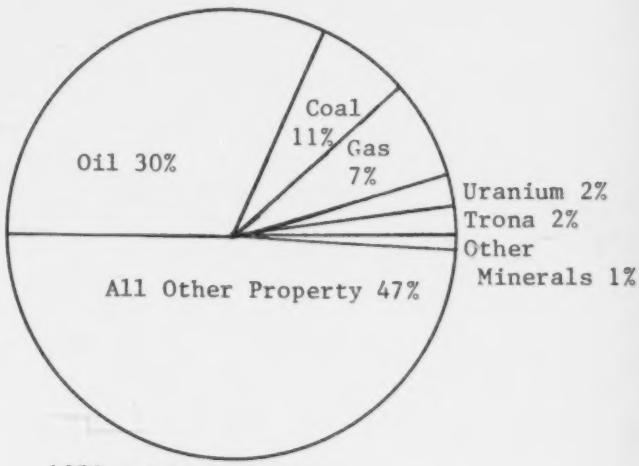
Department of Economic Planning and Development
Herschler Bldg., 3rd Floor
Cheyenne, Wyoming 82002

*These figures are from the Oil and Gas Conservation Commission, rather than Ad Valorem Tax Division, due to the change in reporting requirements adopted by the 1980 Legislature.

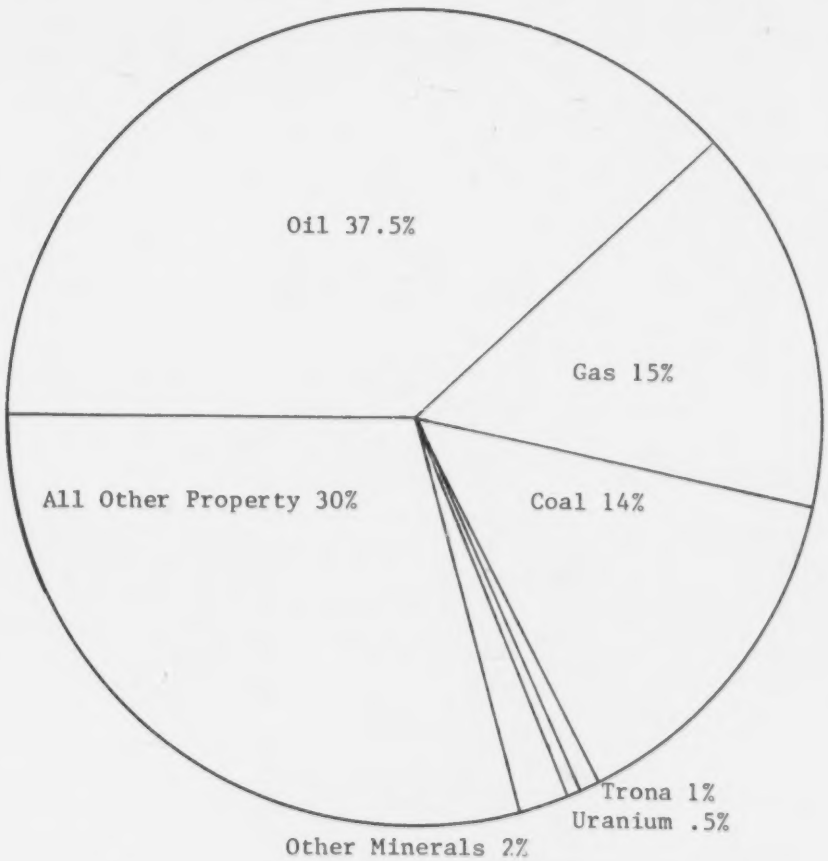
TOTAL STATE ASSESSED VALUATION 1974, 1979 and 1984



1974 Total Valuation
$1,708,945,746



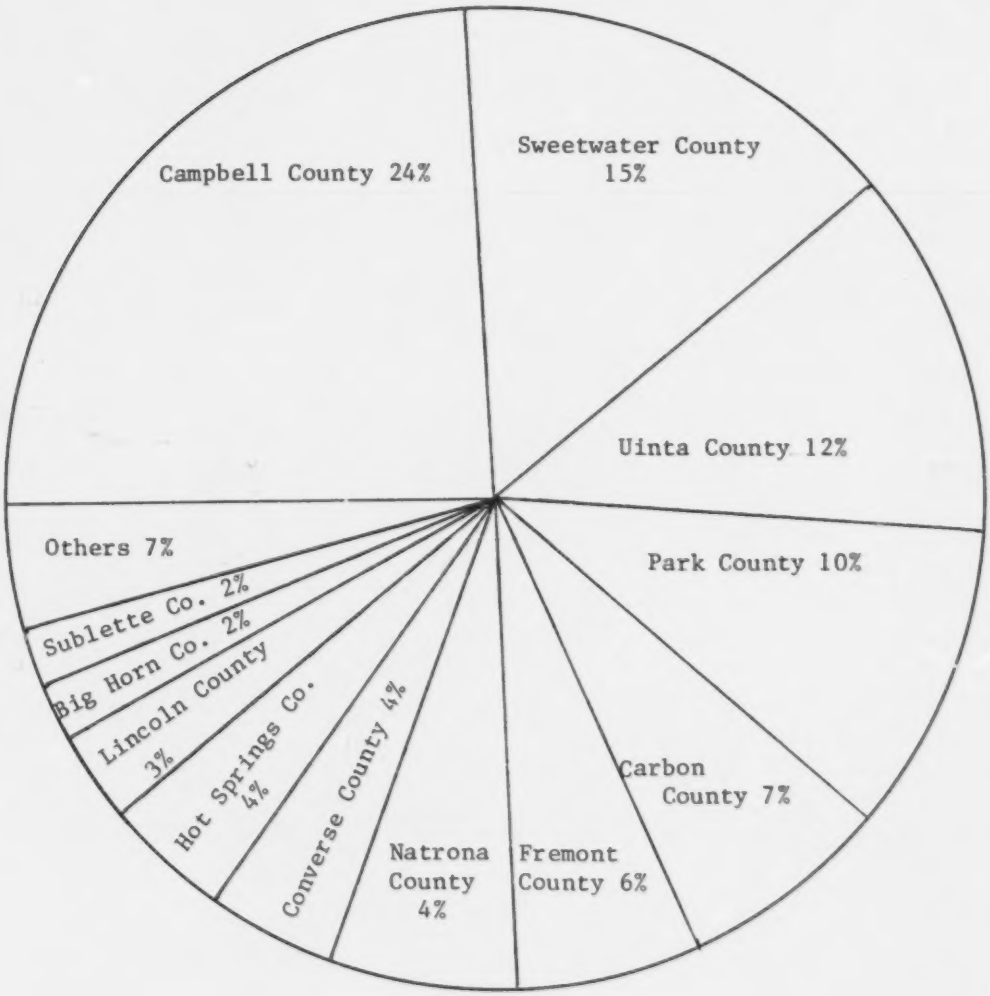
1979 Total Valuation
$3,702,626,530



1984 Total Valuation
$7,945,490,912

TOTAL STATE ASSESSED MINERAL VALUATION 1984

$5,577,786,192



WYOMING MINERAL INDUSTRY

TAX TABLES

The ten tables in this section illustrate the tax situation for the Wyoming Minerals Industry since 1969. The significance of 1969 is that was the year the severance tax on minerals was initiated.

Tables are as follows:

I Assessed Valuation on Production, 1969 - 1984.

II Ad Valorem Tax Paid on Production, 1969 - 1984.

III Assessed Valuation Per Unit of Production, 1969 - 1984.

IV Severance Tax Collections, 1969 - 1984.

V Severance Tax Rates, 1969 - 1984.

VI Severance Tax Distribution, 1983.

VII Sales and Use Tax - Fiscal Year.

VIII Government Royalty.

IX Summary Table.

X Mineral Income to the State, 1971 - 1984.

WYOMING MINERAL COMMODITIES REVIEW
1984

BENTONITE

Bentonite is a clay mineral which is the result of the alteration of volcanic ash. Wyoming bentonite originated from volcanic ash ejected in western Wyoming and Idaho during the late Cretaceous period about 120,000,000 years ago. Prevailing westerly winds blew the ash eastward and deposited it in the areas now occupied by bentonite deposits. Wyoming bentonite occurs in the Big Horn Basin, the southern Powder River Basin, and along the western edge of the Black Hills in the northeastern corner of the state.

Bentonite is a clay mineral composed of microscopic platelets consisting of layers of aluminum hydroxide held between layers of silicate atoms. These platelets are stacked one on top of the other. Water can penetrate between layers of platelets, causing the entire structure to swell. Wyoming bentonite has sodium atoms interspersed between these layers of platelets at intervals. Other types of bentonite have calcium between the platelet layers. Sodium bentonite has greatly increased swelling characteristics. Wyoming sodium bentonite, when wet, increases as much as fifteen times its original volume.

Bentonite was used by area Indians as a bleaching clay and washing agent before the white man ventured into what is now Wyoming. Bentonite bogs or "soap holes" caused the loss of some cattle to pioneers, but it was utilized as an emergency substitute for axle grease, as a curative pack for inflamed horses' hoofs and as waterproofing for the roofs of dwellings.

Bentonite was originally named taylorite for William Taylor of Rock Creek, who first made commercial shipments of the clay in 1888. Dr. S. H. "Sam" Knight, State Geologist of Wyoming, renamed the clay bentonite when he learned that taylorite had previously been used in England as the name for another mineral. The term bentonite comes from the Fort Benton shale member of the Mowry formation, where the mineral occurs.

The first sales of Wyoming bentonite were to eastern plants for use in the manufacture of cosmetics. Production remained at a low level until the 1920's, when bentonite's usefulness as a binding agent in foundry sand and as an additive to oil well drilling mud were first discovered.

The U. S. Bureau of Mines economic mineral publications first separated bentonite from "other clays" in 1931. The Wyoming Ad Valorem Tax Division has maintained separate bentonite production statistics since 1927.

The first bentonite mill in Wyoming was constructed at Cheyenne in 1920. The bentonite used in this plant was mined near Medicine Bow. The first mills near the Black Hills, in the northeastern part of the state, were constructed at Newcastle, Osage, and Upton in 1926. Production began in the northern Black Hills near Belle Fourche in the late 1930's. Later, other high grade deposits were discovered in the Big Horn Basin and the Kaycee area of the Power River Basin.

There are eight companies presently involved in the Wyoming bentonite industry:

1. Kaycee Bentonite and Benton Clay in the Powder River Basin.
2. The Baroid Division of N. L. Industries, Federal Bentonite, International Minerals and Chemical, and American Colloid near the Black Hills.
3. Dresser Minerals, the Baroid Division of N. L. Industries, Wyo-Ben, American Colloid, and Kaycee Bentonite in the Big Horn Basin.

Wyoming bentonite production has risen from 1,141 tons in 1927 to 2,183,865 tons in 1983. The accompanying table shows historical Wyoming bentonite production.

Estimates of remaining Wyoming bentonite reserves vary widely. A report of the American Institute of Mining Engineers gives a figure of 1,149,000,000 tons of in-place reserves, while the 1980 edition of the U. S. Bureau of Mines Minerals Facts and Problems lists reserves of 200,000,000 tons.

Bentonite deposits either crop out at the surface or are buried

shallowly, so mining operations consist of removing any overburden present and loading the bentonite into trucks for transport to a mill. Due to shallow burial and the loose unconsolidated nature of the surrounding sediments, no underground mining of bentonite has been attempted. When the bentonite arrives at the mill, it is segregated into piles according to physical characteristics. Material from these piles are blended to obtain a product with the desired characteristics.

In the mill, the bentonite is first broken into small chunks, screened, and conveyed through a dryer. Temperature of the dryer is critical since temperatures that are too high can destroy the desired properties of the bentonite. Natural gas has been the fuel used in the dryers, but coal and some air drying are now utilized in several operations.

Drying removes about 25% of the moisture in the bentonite. After drying, the clay is pulverized to a variety of size ranges. After sizing, bentonite is either packed in 50, 75, or 100 pound bags or bulk shipped in covered railroad cars.

Currently the single largest market for bentonite is the oil and gas industry, which uses bentonite as a drilling mud additive. 50% of Wyoming bentonite is used in drilling muds. Bentonite's colloidal properties allow heavy well cuttings to be suspended, helps lubricate drilling equipment, cakes the sides of the drill hole to prevent caving, and prevents seeping of ground water into the hole and drilling fluids out of it into surrounding rocks.

The foundry industry consumes 20% of the state's bentonite. Bentonite is used as a molding sand binder. The clay's superior binding properties allow the sand to be formed into shapes that will not fracture or disintegrate during molding operations.

Iron ore pelletizing uses 20% of the bentonite produced. In this application, fine particles of iron ore are bound into pellets for use as blast furnace feed.

The remaining 10% is used in a myriad of applications, a sampling of which are: animal feed, ceramics, water softening, cement manufacture, laxatives, crayons, paint, insecticide, reservoir liner, and medicines.

The Wyoming bentonite industry is facing a decline in markets due to a reduction in oil well drilling, the slump of the steel and automobile industries, and a very sluggish construction activity. Long range prospects are favorable, but bentonite production will very likely be reduced for the next several years.

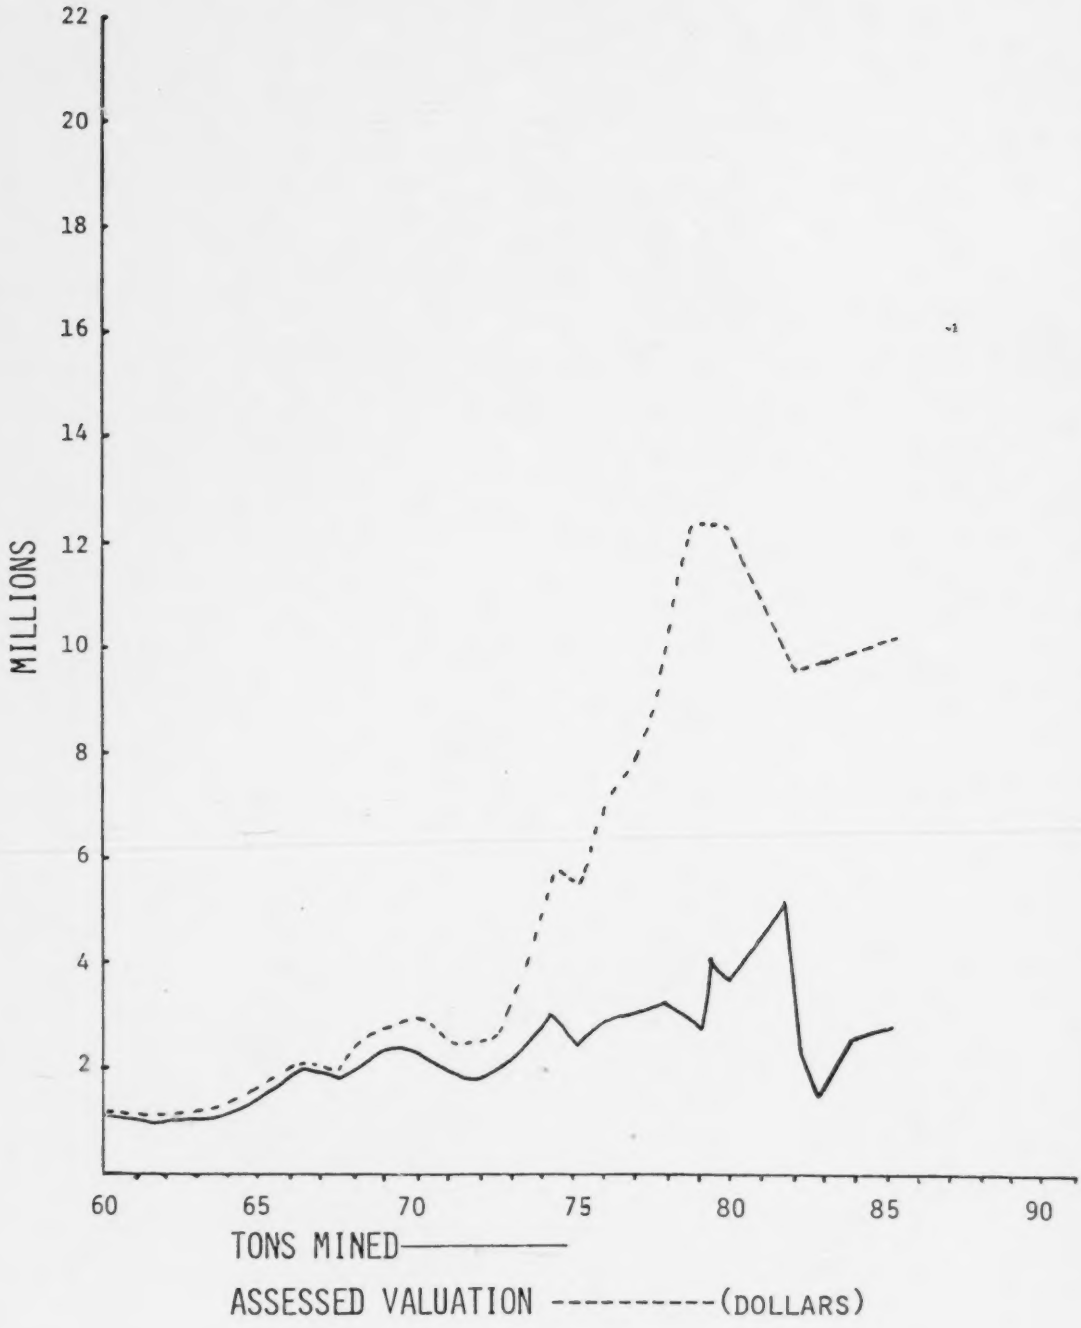
BENTONITE PRODUCTION AND VALUATION

1960 - 1985



COAL

Coal results from the burial and compression of large amounts of vegetation. Increasing depth of burial results in the addition of heat which alters the original vegetation physically and chemically.

Wyoming's coal deposits accumulated during two geologic periods, the later Cretaceous and Early Tertiary, between 75 and 45 million years ago.

During late Cretaceous time, Wyoming was a low land area, periodically covered by a shallow sea which advanced and retreated from east to west. When the sea retreated, low lying coastal swamps developed where extensive vegetation grew, died and accumulated on the swamp bottoms. When the sea re-advanced, the plant material was buried by silts and clays. This cycle was repeated many times, with the earlier deposited material being buried deeper and deeper and ultimately being converted into coal by heat and pressure. Wyoming's Cretaceous coals are commonly thin, seldom exceeding 10 feet in thickness.

Conditions were different in early Tertiary Time, when the other sequence of Wyoming coals developed. The sea had disappeared, and various ranges of the Rocky Mountains had risen. A number of basins developed between these ranges, and large amounts of vegetation accumulated in these basins. These Tertiary coals are typically much thicker then the earlier deposits, with beds of 30 to 100 feet common, and a maximum known thickness of over 200 feet.

Coals are ranked according to composition and heating value. Peat, which consists of lightly compressed dried vegetation, is not considered a coal, although it is used as a fuel in Ireland and northern England. The ranks of coal are as follows:

Name	Amount of Carbon	BTU Content	Volatiles	Moisture
Anthracite	86 - 98%	16,000 - 20,000	5%	0%
Bituminous	55 - 85%	11,000 - 16,000	25%	20%
Subbituminous	30 - 55%	8,300 - 11,000	40%	30%
Lignite	10 - 30%	4,000 - 8,300	50%	40%

These ranks are divided into smaller categories in detailed classifications. Wyoming's coal is subbituminous in grade. It contains more moisture and less sulphur than many equivalent coals from the east and midwest.

The first written account of coal in Wyoming was made in 1843 by Captain John C. Fremont, "The Pathfinder". He referred to the appearance of coal in what was probably Cumberland Gap, near Kemmerer.

Captain John R. Stansbury, U. S. Army Corp of Engineers, reported seeing large outcrops of coal near Rock Springs and at Point of Rocks, twenty-five miles east of Rock Springs, in 1852.

The first use of Wyoming coal was made by the Army to heat winter quarters and in stage line forges in the mid-1800's.

The Union Pacific Railroad began prospecting for coal along its line in Wyoming in 1867, and the first coal mined by the railroad was 650 tons taken at the now abandoned Town of Carbon in 1868.

In 1908, forty years after the first production, coal mining was the leading industry in Wyoming, with a production of over six million tons, one-third of it from the Rock Springs area.

The Kemmerer Coal Company opened mines near Kemmerer about the turn of the century, and Kemmerer Coal is still operating at the present time, the longest continuous operation in the state.

Production increased up to 1947, when eight million tons were produced in the state, mostly from mines in the Hanna, Rock Springs, and Sheridan areas.

It was at this point that the railroads began the change from steam to

diesel locomotives, and as demand for railroad coal decreased, Wyoming production followed it downward. The bottom was reached in 1959 when the state produced less than two million tons.

Beginning in the mid-1960's, interest in Wyoming coal, as a fuel for thermal electric generation plants, began to increase. This interest was sparked primarily by two factors, physical properties of the coal, and its cost. The physical property of Wyoming coal, which made it attractive to power plant operators, was its low sulphur content, which ranges between 0.5 and 1.5 percent sulphur. This constrasts with eastern coals which range from 5 to 9 percent sulphur. The ability to burn Wyoming coal without installation of expensive exhaust gas scrubbers, more than compensated for other detrimental properties, namely low heat value and high water content.

Because virtually all Wyoming coal was strip mined, its cost of production was much less than deep mined eastern coal. In addition, large machinery and the latest technology greatly increased worker productivity, which lowered the price further.

At present, there are twenty-five active Wyoming coal mines: twenty-four surface and one underground. These mines are concentrated in only a few areas: the Hams Fork Coal Region in Lincoln County, the Rock Springs Coal Region in Sweetwater County, the Hanna Coal Field in Carbon County, the Powder River Coal Region in Converse, Campbell, and Sheridan Counties, and one mine in the Big Horn Coal Field of Hot Springs County.

The Powder River Basin accounts for 70% of Wyoming's production and boasts the biggest surface coal mines in the nation: Amax's Belle Ayre Mine and Atlantic Richfield's Black Thunder Mine. Information on individual mines is available from the State Geological Survey in Laramie or the Minerals Division of DEPAD.

Wyoming coal production has increased over 14 fold since 1971 under the

impetus of power plant demand. The history of Wyoming coal production is given on the accompanying table.

The future of the Wyoming coal industry is uncertain. Several factors mitigate against Wyoming coal:

1. With the requirement of SO_2 scrubbers on all power plant smoke stacks, regardless of the sulphur content of the coal being burned, eastern and mid-western utilities are leaning toward local, higher sulphur, higher BTU coal to fuel their boilers.

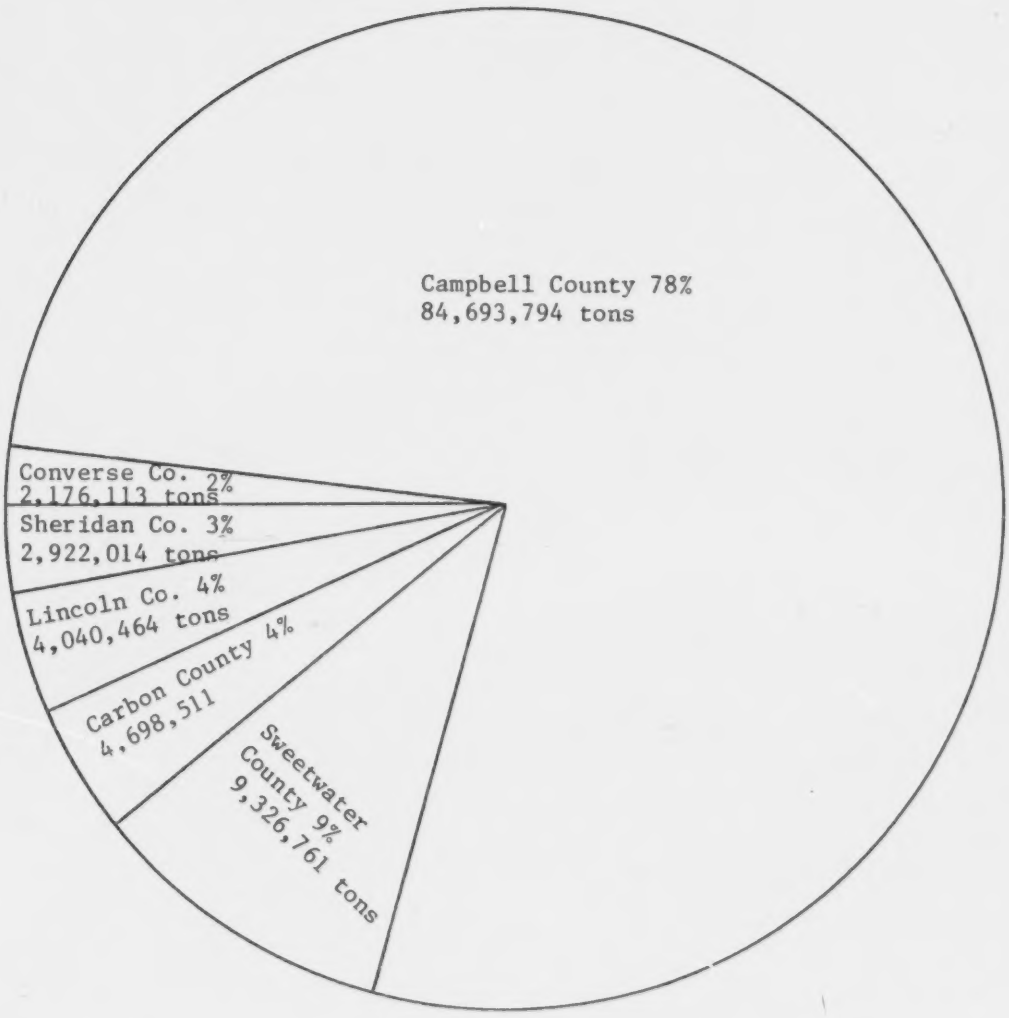
2. Freight rates have reached the point where it costs up to three times as much to transport the coal as the cost of the coal itself. Under these circumstances, local coal becomes much more attractive.

3. The virtual disappearance of the Wyoming coal conversion industry has very much reduced projected in-state coal consumption.

4. Reduced electric power demand has resulted in the cancellation of generating units or entire power plants, significantly reducing potential customers.

Given these negative developments, Wyoming's coal industry is turning its attention toward new markets. One proposed new mine will emphasize the domestic market, an area of small relative demand but one which the existing large mines are not equipped to serve. The most attractive new outlet for Wyoming coal is the export market, primarily the so-called Pacific Rim nations of Japan, China, Taiwan, and the Phillipines, along with Mexico.

1983 COAL PRODUCTION



Total State Production 1983
107,902,764 Tons

HISTORICAL COAL PRODUCTION

Year	Tons	Year	Tons

IRON ORE

Iron is the backbone of our modern industrial civilization. Man has utilized iron for many centuries, first in the uncombined native form and later by smelting from different ores. Alloying with various elements has greatly improved iron's versatility and usefulness to society.

Three types of iron-bearing deposits have been mined in Wyoming. Magnetite (iron oxide) was mined in Albany County for heavy aggregate several years ago. Hematite (hydrated iron oxide) was mined for many years at the Sunrise Mine in Platte County. Taconite was produced by U. S. Steel at Atlantic City.

Wyoming's iron ore industry began in 1870, when hematite was mined north of Rawlins for use as a paint pigment and as a fluxing agent in an early day ore smelter.

Mining commenced on a commercial basis in 1901 when hematite was shipped from an open pit operation near Sunrise in Platte County. This ore was shipped to Pueblo, Colorado, for use in the blast furnaces of the Colorado Fuel and Iron Corporation. The Sunrise Mine changed to an underground operation in the 1930's, due to changes in the ore body.

Between 1963 and 1971, U. S. Agregate operated an iron ore mine in Albany County near Laramie. This mine produced a titaniferous magnetite which was used as a heavy aggregate in such applications as ship ballast.

The U. S. Steel Corporation started production at its open pit mine/beneficiating complex at Atlantic City in Fremont County in 1962. This mine produced taconite which, after beneficiation, yields hardened pellets of high magnetite ore which is used as a direct charge in blast furnaces. The pellets produced at Atlantic City were hauled by rail to the Geneva Steel Works near Provo, Utah.

The United States Bureau of Mines estimated that 99.6% of U. S. production is used in cement, paint, concrete, aggregate, ferro alloys, and animal feed.

Wyoming, at present, has no active iron ore industry. The United States Aggregate operation in Albany County has been closed for ten years. In July, 1980, the Colorado Fuel and Iron Corporation closed the Sunrise Mine due to the depressed state of the steel industry. U. S. Steel Corporation closed their Atlantic City operation indefinitely on October 1, 1983, for economic reasons and environmental problems at their Geneva, Utah foundry.

A history of Wyoming iron ore production is provided on the accompanying chart.

NATURAL GAS

Pure natural gas is composed of the simplest hydrocarbon, methane, CH_4. Natural gas, as it comes from the well, contains a number of different substances, including: ethane, propane, butane, and pentane (hydrocarbons), also carbon dioxide, helium, hydrogen, sulfide, and nitrogen.

Natural gas processing plants remove impurties in the gas and/or compress it to increase density in order to reach the heating standards of commercial gas. The materials removed from the gas by these plants are often valuable in themselves. Propane and butane are used as fuels, while ethane, pentane, and suplhur are utilized by the chemical industry. Hydrogen and helium are important industrial gases, while nitrogen, though often simply vented to the atmosphere, is being reinjected in secondary oil recovery in the Overthrust Belt. Carbon dioxide is also utilized in secondary oil recovery, as well as serving as an important refrigerant when in the liquid or solid form.

Natural gas occurs in three ways:

1. Free natural gas unassociated with crude oil.
2. Associated gas overlying and accompanying crude oil in the same reservoir.
3. Dissolved gas, which is gas in solution with the oil under reservoir conditions.

Pipeline quality natural gas, has a heating value of about 1,000 calories per cubic foot. It burns with a bright flame, and the products of its combustion are carbon dioxide and water vapor. The high BTU output, plus the benign combustion products, make natural gas an excellent domestic fuel.

Wyoming has produced some natural gas since 1903, with early production coming from the Wind River and Big Horn Basins. Before 1918, Wyoming's natural gas production was included with Utah and Colorado, not allowing an individual state breakdown.

Wyoming natural gas production has increased steadily since 1918. Currently the Green River Basin leads the state's geologic provinces in natural gas production, followed by the Wind River and Powder River Basins. Production from the Overthrust Belt, in the southwestern part of the state, is reaching significant proportion and will continue to increase.

Wyoming currently ranks seventh in natural gas reserves in the United States. The three leading states, Texas, Louisiana, and Alaska, alone, account for about three-fourths of the total reserves.

Wyoming is sixth in natural gas production behind Texas, Louisiana, Oklahoma, New Mexico, and Kansas, in that order.

Industrial, commercial, and domestic heating and a fuel for industrial processes have always been, virtually, the only markets for Wyoming natural gas.

The accompanying table shows historical Wyoming natural gas production.

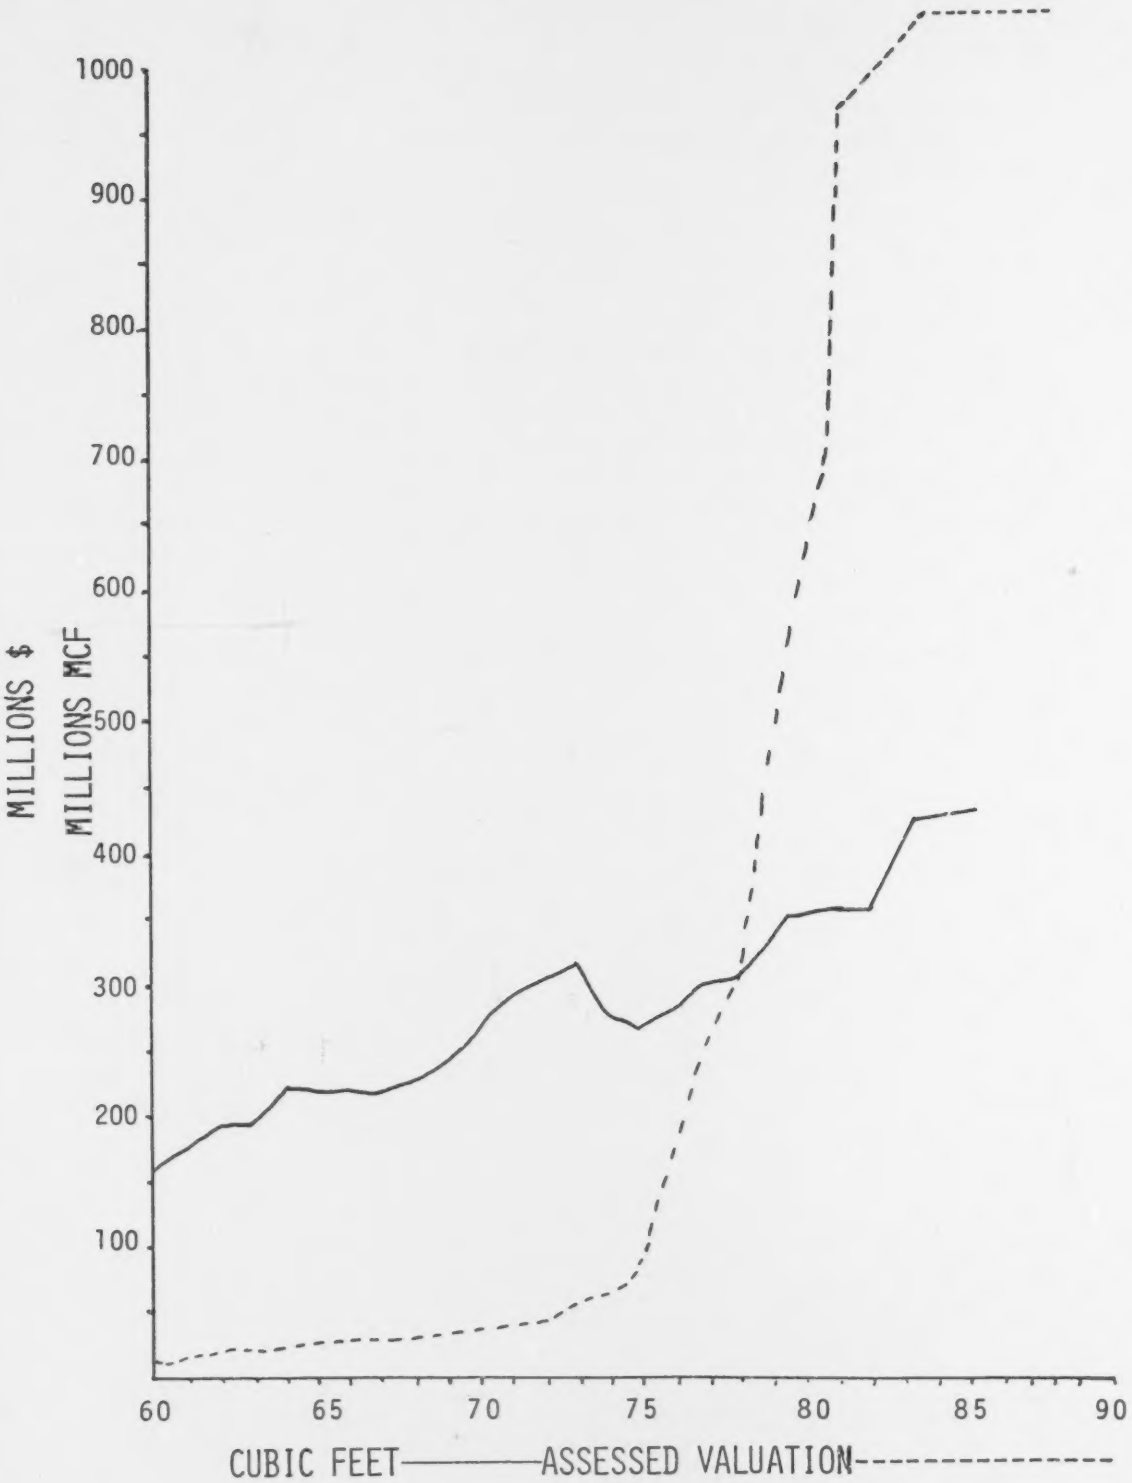
NATURAL GAS PRODUCTION AND VALUATION

1960 - 1985



PETROLEUM

The first recorded reference to the occurrence of oil in Wyoming dates back to 1833, when Captain Bonneville visited the "Great Tar Spring" on the Popo Agie River near present day Lander.

The first commercial marketing of oil occurred in 1851 from an oil seep on Poison Spider Creek, west of present day Casper. Records indicate that Jim Bridger, Kit Carson, and others mixed the oil with flour and sold the product to settlers as axle grease.

The first oil field was discovered by Mike Murphy in 1884, when he drilled a 300 foot well near the "Great Tar Spring". This field, Dallas Dome, is still producing oil, 99 years after its discovery.

Pennsylvania Oil and Gas Company built the first small refinery in Wyoming at Casper in 1895. During the period 1900-1920, drilling revealed several of the state's largest fields, including Oregon Basin and Elk Basin in Park County, Garland in Big Horn County, and Lost Soldier in Sweetwater County.

The lack of nearby markets and the high cost of transporting oil by rail, resulted in low demand for Wyoming oil, and crude prices dropped to as low as 10¢ per barrel in the 1930's. It was not until World War II that development moved into full swing. This expansion continued into the 1970's.

Oil is derived from the alteration of organic matter by heat and pressure. Petroleum originates in sedimentary rock environments, but may migrate to other locations, so that there are oil reservoirs known from volcanic and metamorphic rock sequences as well. Most oil is found in sedimentary rocks, in occurrences which may be divided into structural or stratigraphic traps. A structural trap is one where the oil is maintained in place by mechanical means, such as, folding, faulting, or some combination of the two. Stratigraphic traps involve a change in rock type, from permeable to impermeable, with the oil held in the

permeable portion. A stratigraphic unit which changes from a sandstone (permeable) to a shale (impermeable) is an example of a stratigraphic trap. Most of the early discoveries in Wyoming were in large structural traps with obvious surface expression. Modern exploration is focused on deep, subtle structures using sophisticated seismic techniques to discover new reserves. The delineation of stratigraphic traps is based on careful analysis of trends and rock types along with the application of interpretation and imagination by petroleum geologists.

Reservoir rocks in Wyoming range from Tertiary to Precambrian in age. In general, fields in stable interior basin areas are characterized by stratigraphic traps and produce from younger (Cretaceous and Tertiary) formations. Fields in more highly deformed basin margins are usually characterized by structural traps, and production is from older rocks.

The largest oil producing regions in Wyoming, in order, are: the Powder River Basin, Green River Basin, Big Horn Basin, Overthrust Belt, and Wind River Basin.

In 1983, a total of 1,400 wells were drilled in Wyoming: 967 development wells, and 433 exploration wells. The majority of both exploration and development wells over the past ten years have been drilled in the Powder River Basin.

Early oil production in Wyoming peaked in 1923, after discovery and development of large fields, such as: Salt Creek, Elk Basin, Oregon Basin, and Hamilton Dome. A long period of decline followed these early discoveries until the second World War led to a resurgence which continued to 1970, when the maximum annual production of 155,743,349 barrels was recorded. Since 1970 production has been steadily declining, due to depletion of the old large fields, like Salt Creek. At present, over 50 percent of Wyoming's production comes from ten large fields which average 51 years in age. Newer discoveries

in the state are concentrated primarily in Campbell County (Hilight, Raven Creek, Hartzog Draw fields) and the Overthrust Belt.

Wyoming ranks sixth in crude oil production, behind Texas, Alaska, Louisiana, California, and Oklahoma. However, it dominates Rocky Mountain production, with 44% of the production from the area, and 64% of the reserves.

The dominant use of petroleum is as a fuel for internal combustion engines or industrial and residential heating. However, petroleum derivatives are used to manufacture many kinds of lubricating and hydraulic fluids, fibers, medicines, plastics, and a number of other products, ranging from paints to synthetic rubber.

Although production has been slowly declining, valuation of oil production in Wyoming has risen dramatically since the initiation of OPEC price increases in the early 1970's, and especially since decontrol of domestic oil prices in 1980. In 1981, oil production accounted for 44% of the total state valuation, some 3.6 billion dollars. Valuation will stabilize or even decrease in the short term, but petroleum will remain the state's most valuable mineral product.

Currently, six refineries are operating in Wyoming with a total capacity of 175,000 barrels per day. These refineries can process less than half of Wyoming's daily crude oil production, the remainder being transportated by pipeline to neighboring states.

The most recent estimate of discovered oil reserves in Wyoming, made by the American Petroleum Institute, reports a total state reserve of 808 million barrels. This figure has been declining steadily since 1971, and although new discoveries in the Overthrust Belt will slow the deline, the downward trend will continue.

Given new exploration techniques, along with enhanced recovery methods

which are coming into increasing use, Wyoming will continue to lead the Rocky Mountain region in oil production for some time. If oil shale utilization ever reaches large scale fruition, Wyoming will be a significant oil producer well into the next century.

TRONA

The world's largest deposit of trona is found in Wyoming's Green River Basin. From the deposit, the state produces about 95 percent of the nation's supply of natural soda ash. Several deposits of natural soda ash are known in the western United States, but only Wyoming and California have active mines. Deposits have also been identified in several other countries, but the only one currently producing is Kenya.

Trona is a water-bearing sodium bicarbonate compound with many uses. Trona originated as a precipitate from a large fresh-water lake, Lake Gosiute, which covered as much as 15,000 square miles of surface in southwestern Wyoming. The trona was precipitated when Lake Gosiute underwent a period of restricted circulation and became highly saline at the same time as elevated temperatures resulted in increased evaporation.

More than 40 individual beds of trona underlie an area of about 1,300 square miles. It is estimated that some 50 billion tons of mineable trona, plus an additional 30 to 40 billion tons of marginal trona, are contained in these beds.

In 1938, Mountain Fuel Supply Company drilled an oil and gas test well northwest of Green River, Wyoming, and discovered a brine rich in trona. Exploration by the Union Pacific Railroad, in 1940-1942, indicated the presence of extensive reserves of trona. In 1946, Westvaco, the predecessor of FMC Corporation, sank a 1500 foot shaft to the main trona deposit and constructed a pilot refinery at the surface. The first soda ash was produced by FMC in 1950, with Stauffer Chemical coming on line in 1962, Allied Chemical in 1968, Texasgulf in 1975, and Tenneco Oil Company in 1982.

All Wyoming trona mining is done underground. Room and pillar methods and coal mining equipment, modified to withstand the harder ore, are used.

BEST AVAILABLE COPY

Both conventional and continuous mining techniques have been traditionally used, but recently long wall mining has been successfully employed.

In the past, soda ash was primarily produced synthetically by the Solvay process. This process combines salt (sodium chloride) and calcium carbonate (limestone) to make sodium carbonate (soda ash). Only one plant using the Solvay method is still in operation in this country - in New York State. The Solvay plant shutdowns were the result of high capital, labor, and energy requirements, but the greatest factor was the environmental considerations. For each ton of soda ash produced by the Solvay process, about 1.7 tons of waste are generated, which poses an enormous disposal problem.

Trona is refined by first subjecting the ore to a heat of 400°F to remove water of crystallization, combustible materials, and carbon dioxide. This crude soda residue is then taken into water solution and filtered to remove insoluable residues. The filtered material is then dried. The final product is pure soda ash.

Trona's primary use is in glassmaking, which takes around 55% of the United States' consumption. The chemical industry accounts for 23% of consumption, followed by soap and detergent at 5%, pulp and paper manufacturing at 4%, water treatment at 3%, and 10% in various applications including pharmaceuticals, photography, metallurgy, and petroleum refining.

Wyoming trona production has grown from 29,658 tons in 1950, to 10,542,417 tons in 1983. Valuation of 1983 production was $104,500,003. The short-term future of Wyoming trona is less favorable than earlier predictions, due to slumps in housing and the automobile industry, two prime users of glass, which is trona's most important market. In the longer term, significant growth in Wyoming's trona market would seem to be likely to come from Europe, where most soda ash is currently produced by the Solvay process, which faces the same problems there that led to the shutdown of the industry in this country.

Whatever the demand, Wyoming possesses the resources to meet it. If trona had been mined at the current rates since the year 1 A.D., only 20% of the known reserves would have been depleted, and if mining had proceeded at the same rate since the rise of the first dynasty in Egypt, 50% of the known reserves would still remain untouched.

An annual compilation of trona production in Wyoming is given in the following table.

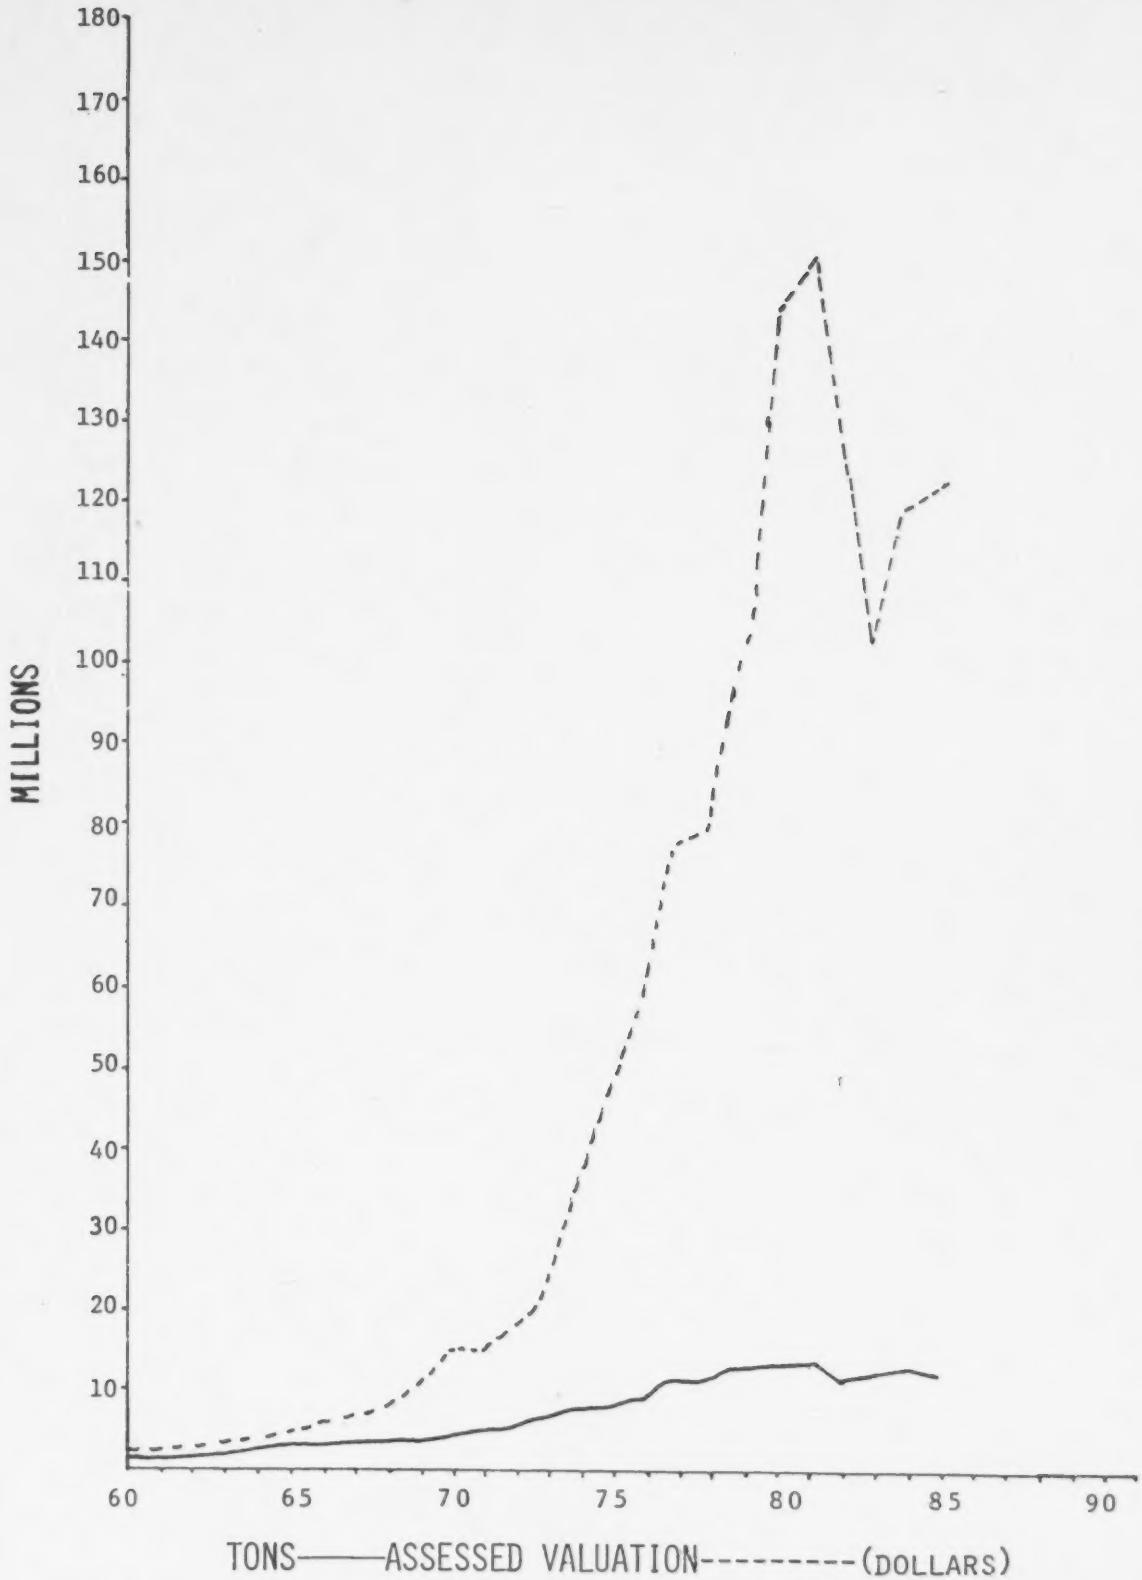
TOTAL TRONA PRODUCTION & VALUATION



URANIUM

Uranium was discovered as an element in 1789 and isolated as a metal in 1842. A few minor uses for uranium salts and medical demand for radium created a small market in the 1920's and 1930's. So little was known about possible ore sources in the United States that the uranium ore used in the production of the two atomic bombs dropped on Japan came from the Belgian Congo. The Atomic Energy Commission was appointed by President Truman in 1946. In the late 1940's and early 1950's the public was encouraged to prospect for uranium and the first great uranium rush was on.

Uranium is a widespread, though uncommon, primary constituent of crystalline rocks of the earth's crust. As a result of weathering processes, it is often removed from these source rocks and redeposited in sediments. Uranium deposits are known from rocks as old as Precambrian, and as recent as Pleistocene, and all ages in-between.

The most important deposits of uranium in Wyoming occur in permeable sandstones of Tertiary age. The uranium was originally contained in the crystalline rocks which form the cores of the state's mountain ranges. The uranium was leached from these rocks and precipitated in the much younger sandstones.

Uranium ore is recovered by open pit, underground, and solution mining methods. Open pit and underground mining is carried out in the usual manner, the only difference being that the material to be removed is determined by using a scintillation counter to delineate the radioactive ore.

In solution mining, a shaft is drilled into the ore body. Chemicals are introduced down this shaft which dissolve the uranium out of the rock. The uranium-containing solution is removed through another well or wells drilled to the depth of the ore body. The solution on the surface is processed much as the

solutions obtained by conventional milling methods to remove the dissolved uranium. Due to the toxic nature of the solutions used, great care must be exercised in solution mining operations to prevent ground water contamination.

Milling involves grinding and crushing the ore, after which it is treated with acid to take the uranium into solution. The leachate is treated with various chemicals to concentrate the uranium and simplify it chemically. The final concentrate is evaporated to yield "yellow cake". The yellow cake consists almost entirely of uranium 238 and a small percentage of uranium 235, the fissionable isotope. The uranium must be enriched to around 3.5% U 235 for power reactor use, while weapons grade material has a U 235 content of over 90%. The yellow cake is shipped to various conversion and enrichment facilities to be upgraded to the required level.

The primary uses of uranium are as fuel for nuclear reactors and national defense. The drop in power demand coupled with uneasiness over plant reliability have combined to slow the construction of nuclear power plants, and greatly reduce the requirements for uranium. Defense requirements are difficult to determine, but new weapon construction plus upgrading of existing stock piles (nuclear warheads deteriorate through time) has increased, though not enough to increase demand significantly. Other uses for uranium are in X-ray tubes, ultraviolet lamps, glass colorants, ceramics, and steel.

Wyoming's first production of uranium occurred in 1953, when 5,156 tons of ore were mined. The largest production of 5,517,070 tons was attained in 1978. Wyoming ranks second to New Mexico in both uranium production and amount of reserves. The history of Wyoming uranium production is given in the accompanying table.

The Wyoming uranium industry mirrors the current slump affecting the entire industry. From 19 operations employing over 5,400 workers in early 1980, the industry has shrunk to 4 operations employing about 1,200. Yellowcake, which

had reached spot market prices of $40.00 per pound in mid-1980, was at $17.50 per pound in 1984. The current market price is $21.25 per pound. This increase in value probably reflects reduction in mine stock piles and adjustments due to mine closures rather than any increase in real demand. Production is projected to show a significant near-term decline. Estimates of when the industry will recover vary, but 1986 to 1990 is the range given, and Wyoming's uranium industry will follow the national trend, however it materializes.

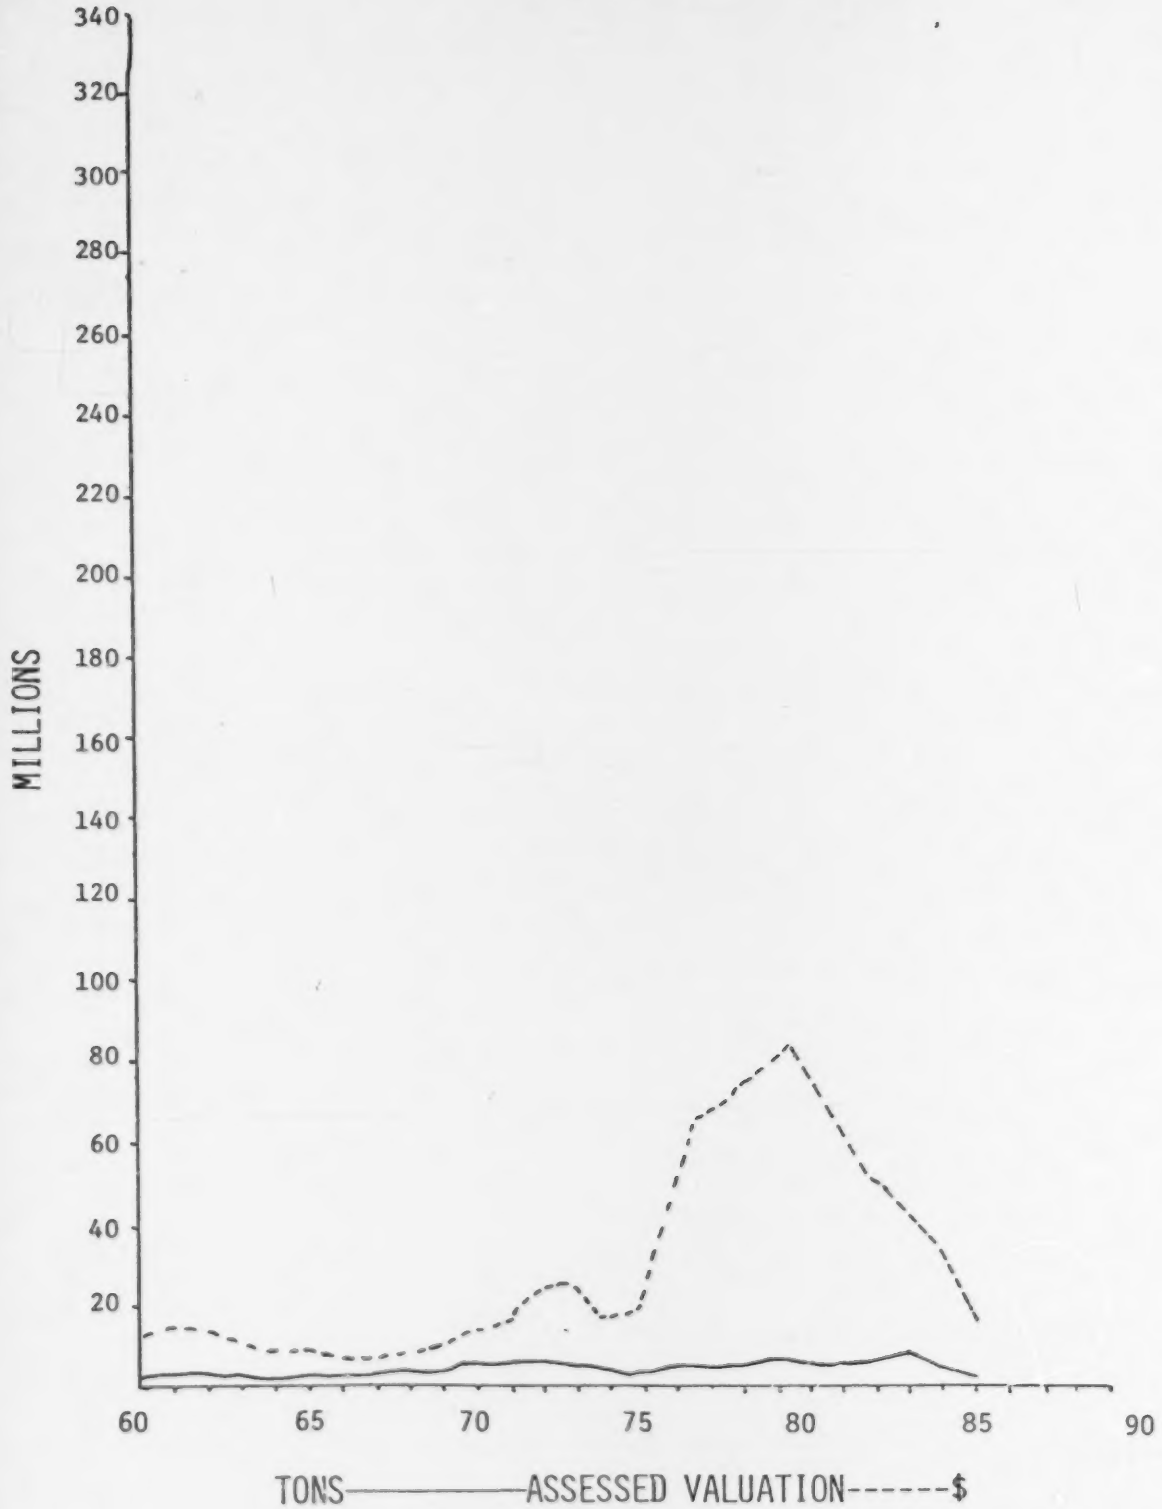
URANIUM PRODUCTION AND VALUATION

1960 - 1985



MISCELLANEOUS MINERALS

COPPER

Copper was the first metal utilized by man over 6,000 years ago. Native uncombined copper was utilized for tools, weapons, and jewelry due to the ease with which it could be shaped.

Currently, over half of the copper produced is used in the electrical industry for wire, equipment, and components. Next to silver, copper has the highest electrical conductivity of any metal. Other uses of copper are in plumbing, instruments, household utensils, decorative items, and coinage.

Copper occurs as the native metal or combined in sulphides, oxides, and carbonates. These secondary compounds are the result of weathering and concentration of copper from its original source in low silica igneous rocks.

Copper mineralization occurs sporadically throughout every mountain range in Wyoming. Copper mineralization is most common in Precambrian rocks, but is found in younger rocks in places such as the northern Laramie mountains and the Hartville uplift.

In the interval between 1899 and 1908, over 23.5 million pounds of copper were produced in Wyoming, mostly from the Encampment district, west of Laramie, and in this period Wyoming was one of the leading copper producing states in the nation. Copper production increased during World War I, mostly from the Hartville area, north of Wheatland. Since that time, Wyoming copper production has been insignificant. Recent speculation concerning reopening of the famous Ferris-Haggerty Mine in Carbon County, along with AMAX Minerals' interest in opening a copper mine in the Kirwin district in the Absaroka Mountains in Park County, are very unlikely to come to pass as long as world copper prices remain at their current low levels.

DIAMONDS

Diamond is composed of carbon, arranged in a crystal structure which makes it the hardest natural substance known. Diamonds were first prized as gemstones centuries ago in India and Borneo. It was not until much later that the applications of diamond as an abrasive in grinding wheels and drill bits, and as wire drawing dies, were realized.

Diamonds are produced in South Africa, the U.S.S.R., Brazil, and the East Indies. No natural diamonds are produced in the United States, although the General Electric Company has produced synthetic diamonds of industrial grade since 1955.

The primary source of diamonds is the mineral Kimberlite, a greenish gray crystalline rock which is the solidified lava conduit of an ancient volcano. Diamonds are produced naturally in the high pressures and temperatures found in pockets of molten rock deep beneath the surface. Exposure of these Kimberlite pipes results in weathering of diamonds from the rock and their concentration in stream gravels. About 50% of the diamonds recovered are taken by placer mining of old stream channels.

Kimberlite pipes occur along the eastern Wyoming-Colorado border. A number of small (less than 2 mm) diamonds have been extracted from these rocks. Cominco American conducted preliminary evaluation work on the deposits in Wyoming but these efforts have been abandoned.

GOLD

Gold has been treasured since ancient times due to its beauty, permanence, and the ease with which it can be worked. In the latter half of the 20th century, it has become a valuable industrial material, with applications in computers, shielding, high performance welding and other uses. Gold's most widespread use remains as a monetary standard. Nearly half of the gold that has ever been mined is in government vaults.

Gold is one of the "noble" metals. It does not combine chemically with other elements. Gold is found in a wide variety of geologic environments associated with various rocks and minerals. Due to its weight and lack of impurities, it is concentrated by stream action into placer deposits where it is recovered by dredging and washing sediments.

Gold has been found in all of the mountain ranges of Wyoming. Past significant mining operations were located in the Wind River Mountains, the Medicine Bow Mountains, and the Sierra Madre Mountains. No mines in these districts were exploited below 400 feet, and many were abandoned while still in the ore body.

Approximately 325,000 ounces of gold have been produced from Wyoming. No operations are currently active, although current gold prices have stimulated renewed interest and exploration.

GYPSUM

Gypsum has been used since ancient times for carving and decoration. The Greeks used it to manufacture plaster, which remains the principle use for the mineral. In the late 1800's a method to retard the setting of gypsum plaster was developed, and this revolutionized the industry by permitting the use of plaster in construction. The development of prefabricated wallboard revolutionized the industry again in the 1960's. Approximately two-thirds of the gypsum currently marketed is in the form of prefabricated products.

Gypsum is precipitated primarily from sea water, but may be deposited in saline lakes or hot springs. It often occurs as a product of volcanic activity and may occur in metallic mineral veins.

Gypsum, in Wyoming, primarily occurs in layers in Permian, Triassic, and Jurassic red beds at various localities within the state. Some gypsum has been mined in Wyoming since the 1890's, but current production comes from mines in Albany, Big Horn, and Park Counties. Virtually all of Wyoming's gypsum output is utilized in the manufacture of wallboard for the construction industry and the manufacturing of cement.

JADE

Jade has been a prized gemstone in China and the Far East for a long time. It is valued for its toughness, ability to take a high polish, and the ease with which is is carved.

The term jade is applied to two different minerals which have roughly similar properties. The mineral jadeite is a sodium-aluminum silicate. It is hard and tough, and varies from white to greenish-white to emerald green. It has been found in Burma, Southern China, Tibet, Mexico, and South America. No jadeite has been found in Wyoming. The second variety of jade is the mineral nephrite, a calcium-magnesium-aluminum silicate. It is not quite so hard or tough as jadeite. Its color varies from olive-green through dark green to black. Light "apple-green" jade is the most valued. It has been found in China, Turkestan, Siberia, New Zealand, and Alaska, as well as Wyoming.

Jadeite occurs in metamorphic rocks in veins and masses. Nephrite occurs as veins in metamorphic rocks. Wyoming jades occurs as veins in Precambrian metamorphic rocks in the southern Wind River Mountains. Boulders and pebbles of jade occur around the southern end of the Wind River Mountains and on the north end of the Laramie Mountains to the east. Although the jade industry of Wyoming is small, it is well known throughout the world and provides some income and/or a hobby for many people.

ZEOLITES

Zeolites are sodium and/or calcium-aluminum silicate minerals that occur in bedded clay deposits or in vesicles in volcanic rocks. They are useful due to their ability to exchange ions with solutions they come into contact with, with their greatest current use being in water softening. It is projected that they will be used on a large scale for extraction of radioactive products from nuclear reactor wastes.

The Beaver Rim area of Fremont County contains layered zeolites bedded with clays exposed over a considerable area. There is no commercial production at this time.

CONSTRUCTION MATERIALS

The major construction materials mined in Wyoming are crushed rock for cement, sand and gravel, and limestone. The cement industry is the largest non-fuel minerals industry in the nation. Cement is vital to the construction and road-building industries and is literally the backbone of modern civilization. Wyoming does have one cememt plant in Albany County.

Sand and gravel is the only mineral commodity which is produced in all 50 states, and coincidentally is the only one produced in all of Wyoming's 23 counties. Its primary uses are as aggregate for concrete and bituminous mixes, for road bases and coverings and as fill. Pure sand is used in glass manufacture, foundry molding, and metallurgical applications.

Limestone is utilized as a building and decorative stone, road metal, aggregate, and in sugar beet factories where pure limestone is used as a source of lime and carbon dioxide in the refining process.

COUNTY MINERAL PRODUCTION AND VALUATION
1984

ALBANY COUNTY

Mineral production in Albany County does not play a significant role relative to the total assessed valuation of the county but production does remain comparatively stable from year to year. Projections for future mineral activity in Albany County indicate there will not be any significant changes in production.

Total assessed mineral valuation in 1984 was $4.7 million, down $400,000 from 1983. This decrease was due to a $2.72 per barrel decrease in oil valuation from $29.77 per barrel to $27.09 per barrel along with a production drop of 1,468 barrels. Production will continue to decline slowly, while valuation will increase over time, though not so rapidly as in the past.

Other commodities produced in Albany County are gypsum and cement rock both by the Monolith Portland Cement Company in Laramie. 15,954 tons of gypsum were produced in 1983, along with 393,647 tons of cement rock.

BIG HORN COUNTY

Sixty-nine percent of the total Big Horn County valuation and 93% of the county mineral valuation is due to crude oil. 1983 production fell by 380,000 barrels over 1982, and valuation fell from $27.10 per barrel to $24.66 per barrel. Oil production will continue to decline while valuation should level off and then show a longer term increase.

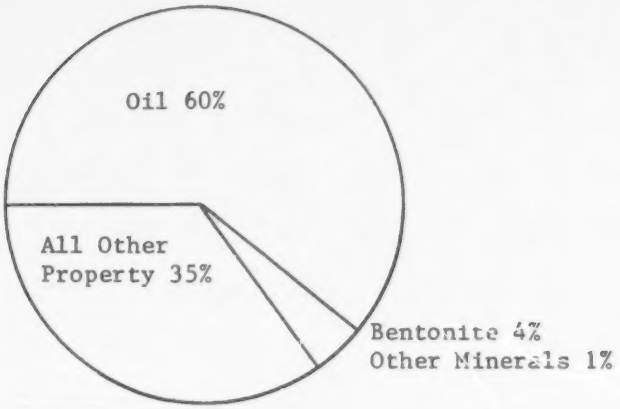
Natural gas production increased in 1983 by over 1.3 million MCF. Production should increase through the mid-1980's.

Bentonite production decreased by 430,000 tons in 1983. A sharp drop in well drilling caused this much of a decrease, along with depressed steel and automobile markets. The bentonite industry will reflect the status of these markets.

Gypsum production will likely stay at a constant level for the next five years, with any fluctuations reflecting trends in the construction industry.

Other minerals produced in the county are clay, sand and gravel.

Big Horn County Valuation 1979 and 1984



1979 Total Valuation $86,047,986

1984 Total Valuation $174,219,591

CAMPBELL COUNTY

Campbell County leads the state in assessed mineral valuation. The 1984 valuation on 1983 production of its oil, gas, coal and other minerals totaled $1,318,276,180 or 24% of the total state valuation on minerals.

Unit valuation of oil rose slightly from $27.79 per barrel in 1983 to $28.00 per barrel in 1984. Total oil valuation fell from $616 million to $589 million, while production dropped by 799,000 barrels. Production will probably continue to decline, while valuation will slowly increase over time.

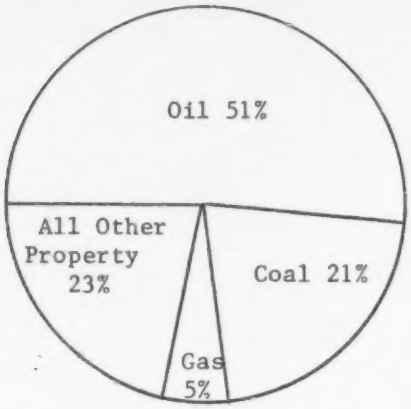
Natural gas production increased in 1983, and this trend should continue due to new finds plus production of gas formerly used in secondary oil recovery.

Campbell County, in 1983, produced 84.7 million tons of coal, 78% of the state total. Projections place Campbell County coal production at 95 million tons by 1986.

There is no active uranium development in the county due to current market conditions.

The Hampshire Energy coal to gasoline project is in an indefinite holding pattern.

Campbell County Valuation 1979 and 1984



1979 Total Valuation $596,173,894

1984 Total Valuation $1,543,579,185

CARBON COUNTY

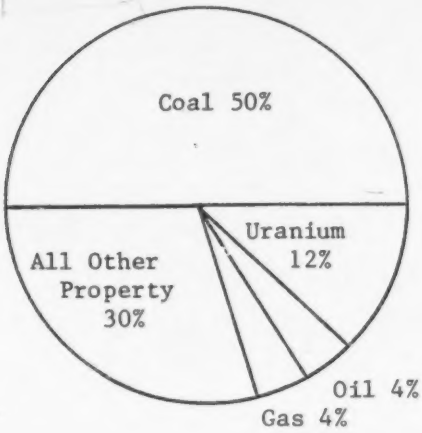
The most valuable mineral produced in Carbon County in 1983 was gas, with a production of 33,073,794 MCF valued at $140,627,065 million.

Coal production was down nearly 400,000 tons in 1983. The soft coal market, along with the expense and difficulty of mining in Carbon County, combine to make it likely that coal production in the county will show a decrease for the next several years.

Carbon County uranium production decreased by almost 134,000 tons in 1983, and further decreases, at least through the mid-1980's are likely.

Oil production showed a decrease of nearly 500,000 barrels in 1983, and the slow down in drilling activity will continue for the near future.

Carbon County Valuation 1979 and 1984



1979 Total Valuation $293,540,934

1984 Total Valuation $474,966,656

CONVERSE COUNTY

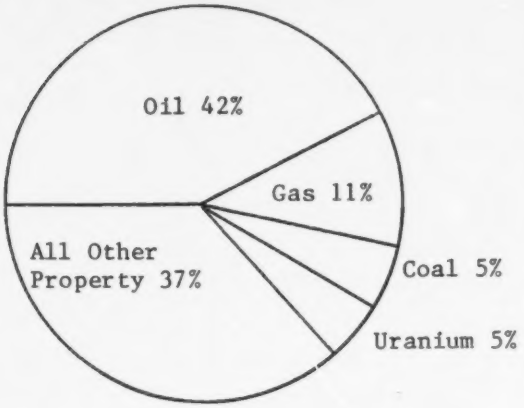
Oil production decreased by over 625,000 barrels in 1983 over 1982. Unit valuation fell from $32.48 per barrel in 1983 to $29.76 per barrel in 1984. As a result, the valuation on oil in 1984 was $168.3 million, a decrease of $35.7 million over 1983. Production will continue to decline, and a leveling off of unit valuation will see oil revenue fall in the county in the next few years.

Natural gas production decreased over 500,000 MCF in 1984. Unit valuation per MCF remained essentially stable. This valuation should continue to rise through the mid-1980's.

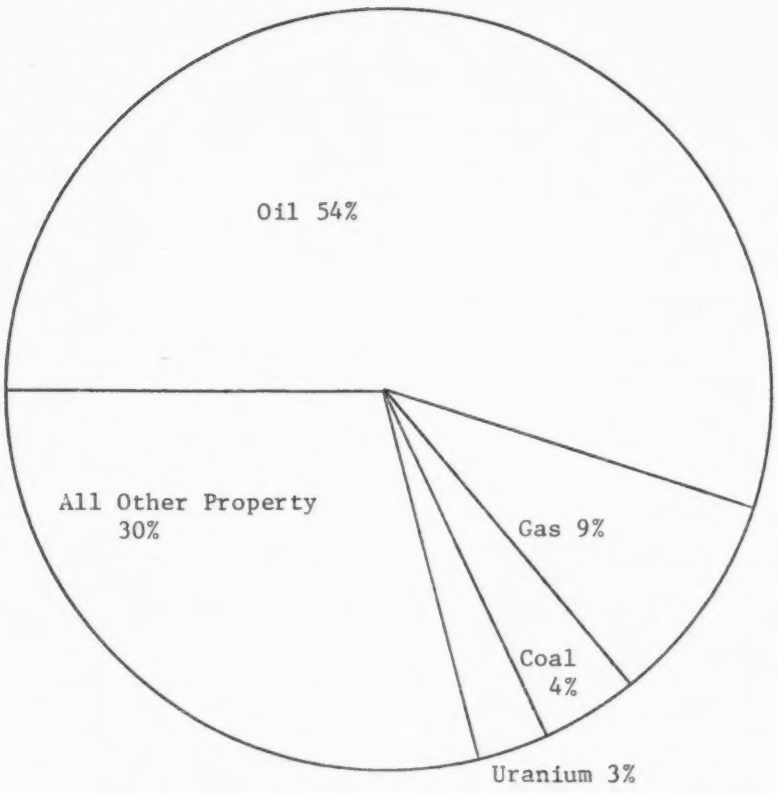
2,684,000 tons of coal were produced in the county in 1983 by Pacific Power and Light to fuel their Dave Johnston Power Plant. This figure will stabilize at 3.2 to 3.5 million tons per year by 1985.

Converse County produced 1,222,000 tons of uranium ore in 1983. This is a decrease of over 100,000 tons compared to 1982. The Bear Creek Mine and Mill of Rocky Mountain Energy is the only currently active uranium operation in the county.

Converse County Valuation 1979 and 1984



1979 Total Valuation $227,652,444



1984 Total Valuation $313,651,261

CROOK COUNTY

Minerals are accountable for 76% of assessable property in Crook County. Over 93% of the mineral valuation is on crude oil production.

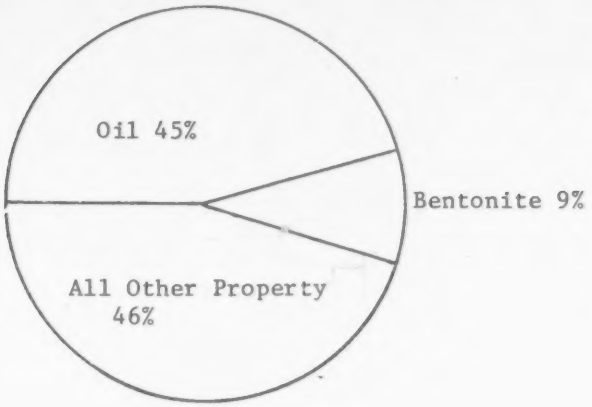
Crook County oil has risen from $7.87 per barrel in 1976 to $25.60 per barrel in 1984. These prices will show a decease over the near term.

Production increased by 236,000 barrels in 1983, while valuation increased only slightly by $31,000. County production will probably remain fairly stable through the mid-1980's.

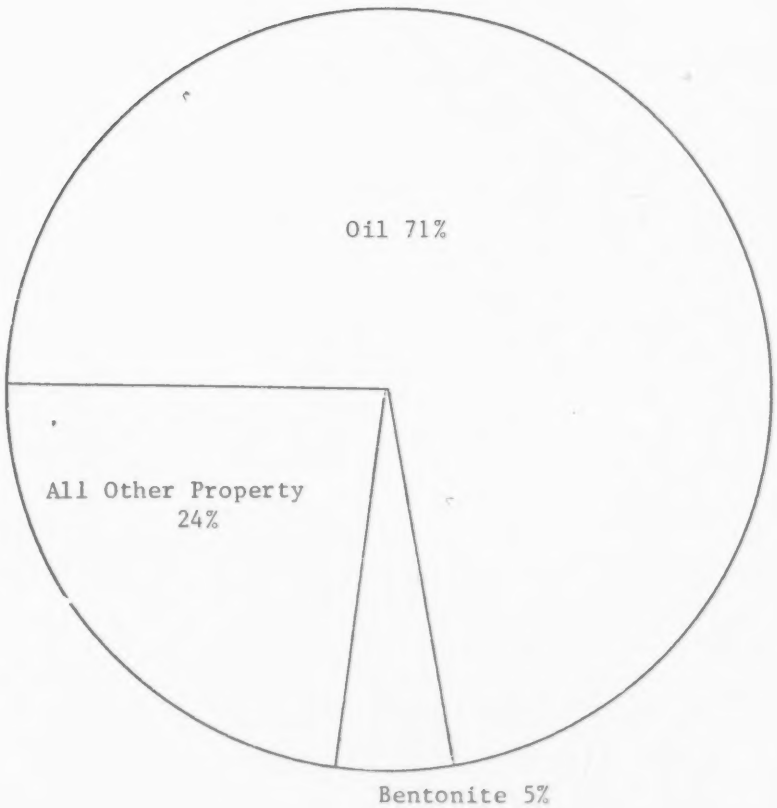
Natural gas production was 72,000 MCF in 1983, a small increase from 1982. Production should stabilize at around 100,000 MCF.

Bentonite production increased by 2,000 tons in 1983.

Crook County Valuation 1979 and 1984



1979 Total Valuation $49,718,677



1984 Total Valuation $114,105,042

FREMONT COUNTY

Fremont County has historically had a diversified mineral industry, producing significant amounts of oil, gas, iron ore, and uranium. The closing of United States Steel's Atlantic City operation will reduce this diversity.

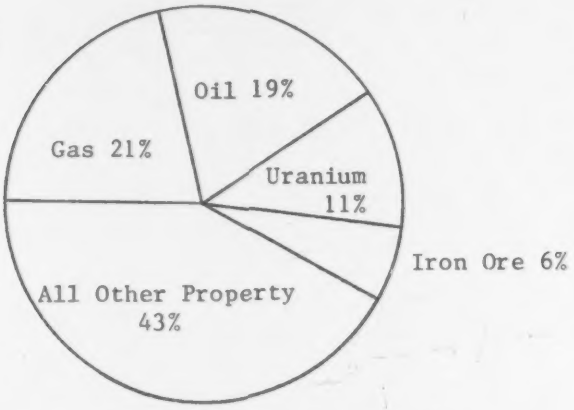
Oil accounts for 43% of the county's mineral valuation. Production increased by 12,000 barrels in 1983, but a unit valuation decrease of $2.51 per barrel resulted in a valuation drop of over $13,700,000. Valuation will increase again in the near future.

Natural gas production decreased by over 11 million MCF in 1983, but this decrease will be greatly slowed.

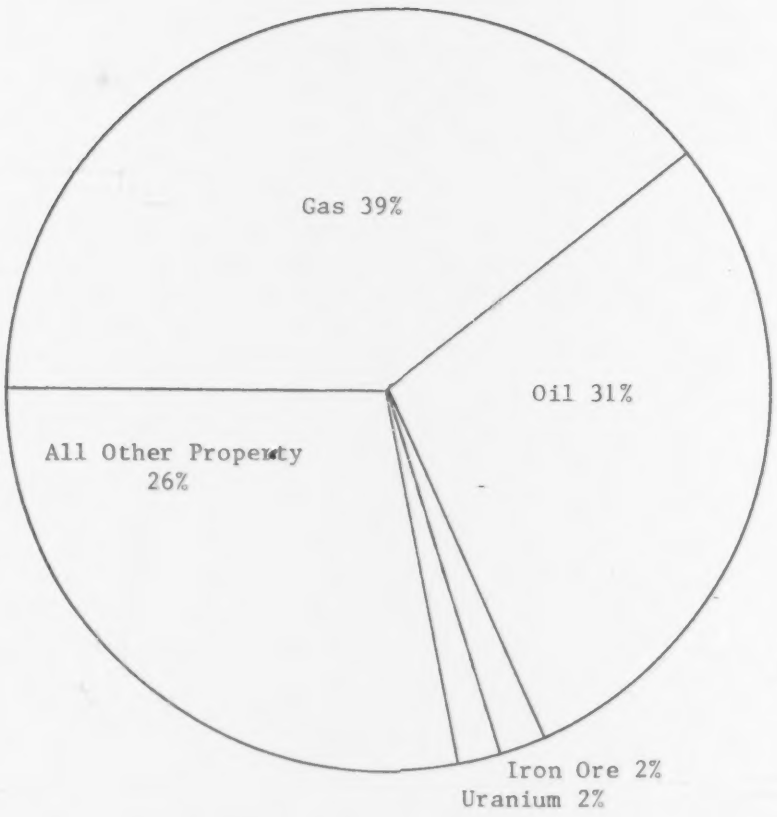
Fremont County was second in the state in uranium production in 1983 producing 780,000 tons. This is a decline of 28,000 tons from 1982, and the trend will continue downward until market conditions improve.

United States Steel Corporation's Atlantic City Mine and Mill closed for an indefinite period on October 1, 1983. This facility was the only iron ore mining operation remaining in the state.

Fremont County Valuation 1979 and 1984



1979 Total Valuation $230,104,026



1984 Total Valuation $466,501,221

GOSHEN COUNTY

Oil, and sand and gravel are the only mineral resources extracted in Goshen County. Production is from two small fields south of Torrington. Production in 1983 was 15,271 barrels, a jump of over 1,200 barrels from 1982.

Goshen County will produce a small amount of oil for some years, but the quantity will likely fluctuate.

Since most of the wells in Goshen County are low production stripper wells, their oil has been uncontrolled for some time. As a result, Goshen County oil has had one of the higher valuations per barrel in the state at $29.98. Even so, this is a decrease of $1.43 per barrel from 1983.

Total county mineral valuation in 1984 was $662,515.

HOT SPRINGS COUNTY

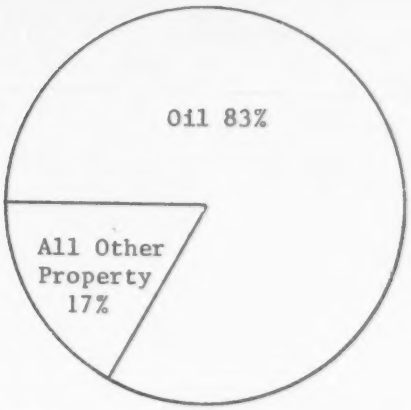
Crude oil accounts for 88% of the total assessed valuation of Hot Springs County. Production has generally declined since the early 1960's but unit valuation has increased at such a rate that valuation has risen dramatically. In 1983, however, oil valuation fell by $2.62 per barrel while production declined by 583,000 barrels. Unit valuations should again rise in the 1985-1990 time range.

Oil production will show a slow decline through the mid-1980's.

Coal production in Hot Springs County decreased in 1983 to 45,107 tons. Applications to increase capacity of the Grass Creek Mine to 700,000 tons per year have been filed, and county coal production should show increases in the next several years.

The county produced 58,000 tons of bentonite in 1983.

Hot Springs County Valuation 1979 and 1984



1979 Total Valuation $101,110,116

1984 Total Valuation $222,732,863

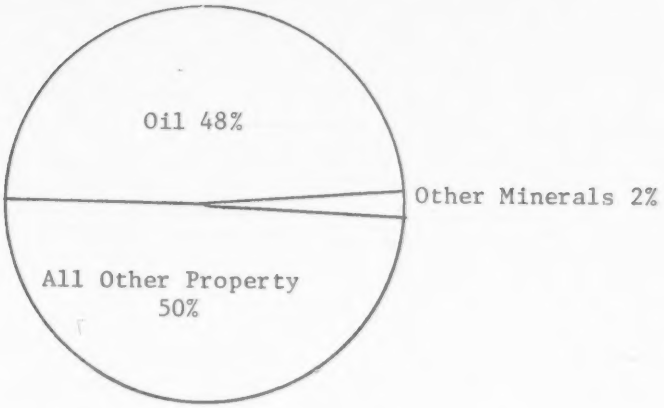
JOHNSON COUNTY

Oil accounted for 96% of the mineral valuation in Johnson County in 1983. Production increased by over 200,000 barrels in 1983, but a decrease of nearly $2.47 per barrel in valuation caused total valuation to remain almost steady. Production will not rise, but unit valuation should show an upturn in the near term.

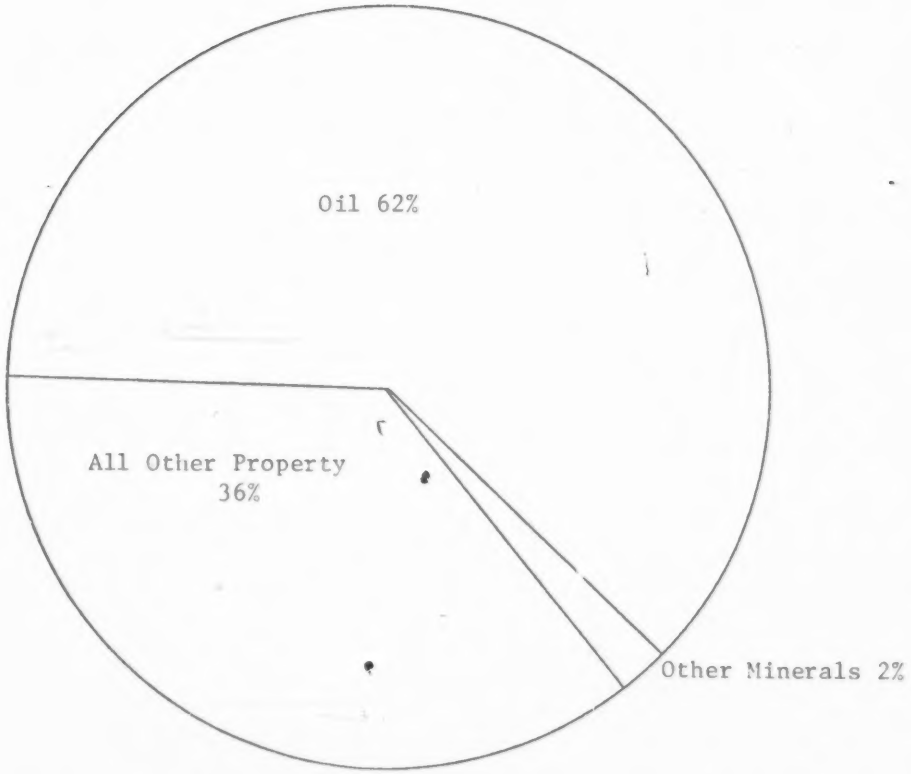
County bentonite production increased by over 82,000 tons in 1983. Bentonite production should rebound in the county through 1985, depending on market conditions.

Texaco owns the extensive Lake DeSmet coal deposits, but has no current development plans.

Johnson County Valuation 1979 and 1984



1979 Total Valuation $65,916,262



1984 Total Valuation $119,215,841

LARAMIE COUNTY

Mineral production in Laramie County in 1983 was divided between oil, sand, gravel, and construction materials in dollar value. Oil production accounted for 86% of the county total of 10.6 million dollars, while construction materials (sand, gravel, and crushed rocks) were responsible for the remaining 14%.

Oil production in Laramie County has been generally declining. However, production in 1983 was 376,000 barrels, an increase of some 97,000 barrels over 1982. Production is projected to decline to around 200,000 barrels by 1985.

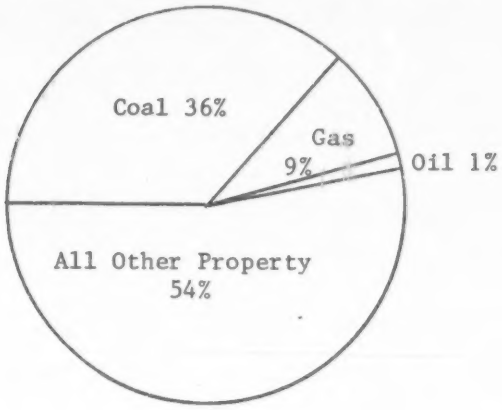
LINCOLN COUNTY

Minerals account for 67% of Lincoln County's valuation. Gas is responsible for 35%, coal for 29%, and oil for 3%.

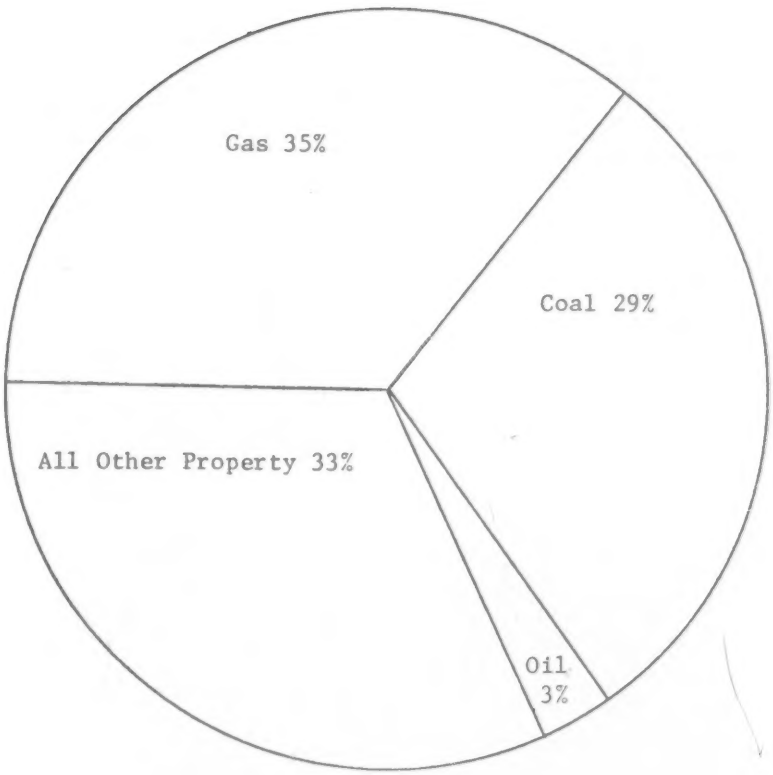
Lincoln County has produced coal since 1875. Coal production in 1983 was 4,040,464 tons, 274,000 tons less than in 1982. Additional production from mines at FMC and Rocky Mountain Energy should increase county production to around 5.5 million tons per year by 1985.

Lincoln County oil production in 1983 was 387,109 barrels, some 147,000 barrels more than 1982. Natural gas production was up almost 3 million MCF from 1982. Overall, gas production in Lincoln County will increase over the next several years, due to Overthrust development. If the Riley Ridge area goes into full scale production, Lincoln County's natural gas production will rise dramatically. The likelihood of that development is dependent on the difficulty of cleansing the gas of CO_2, as well as the effect of total decontrol in 1983 on prices, if it is approved.

Lincoln County Valuation 1979 and 1984



1979 Total Valuation $138,668,877



1984 Total Valuation $271,935,699

NATRONA COUNTY

Minerals are responsible for 45% of the total assessed valuation in Natrona County. Oil accounts for 89% of the mineral valuation.

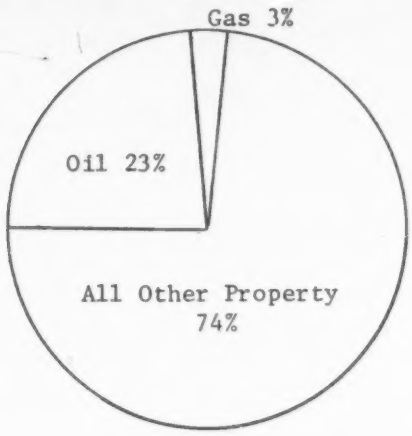
Oil production in Natrona County increased slightly in 1983. 1983 production (7.1 million barrels) is up 300,000 barrels from 1982. However, valuation on oil production decreased by $7 million. This drop in valuation will stabilize and be reversed in the near future.

Uranium production increased by 16,000 tons in 1983 in the county. Only the Bear Creek operation of Rocky Mountain Energy is currently active. Future activity will be dictated by market conditions.

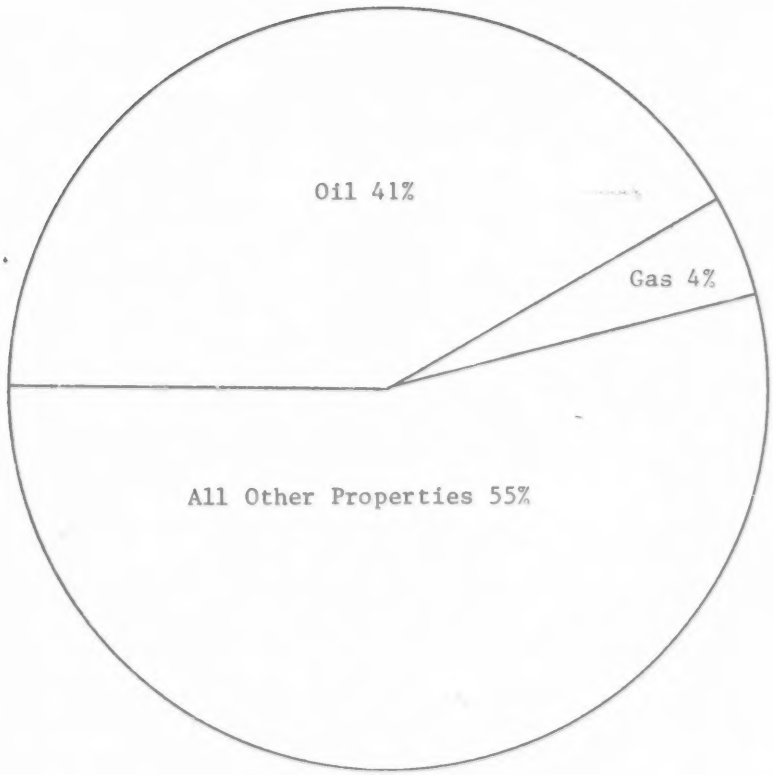
Bentonite production increased by 10,000 tons in 1983. Benton Clay Company and Kaycee Bentonite Company operate mines in Natrona County. Output could reach 100,000 tons per year by 1985.

Other mineral products mined in Natrona County are sodium sulfate, sand and gravel.

Natrona County Valuation 1979 and 1984



1979 Total Valuation $246,256,286



1984 Total Valuation $508,655,018

NIOBRARA COUNTY

Niobrara County's oil production in 1983 fell from 1,234,192 barrels to 1,165,753 barrels. Assessable natural gas production fell by 55,000 MCF. Niobrara County is one of the smaller producers in the state, accounting for only about one percent of both the state's oil and natural gas production. In 1983, unit valuation of oil fell by $2.80 per barrel while gas value dropped $1.35 per MCF. Production is so small that the county is not a reliable indicator of trends in state production.

PARK COUNTY

Park County remains the largest oil producing county in the state. 1983 taxable production was 21,371,025 barrels, or 19% of the state total, a decline of over 600,000 barrels over 1982. Most of Park County's production comes from the Oregon Basin and Elk Basin fields. Oregon Basin has produced over 250 million barrels since its discovery in 1912, while Elk Basin has produced over 375 million barrels since 1915. Production has been declining since the late 1960's. These fields will become increasingly less productive through time.

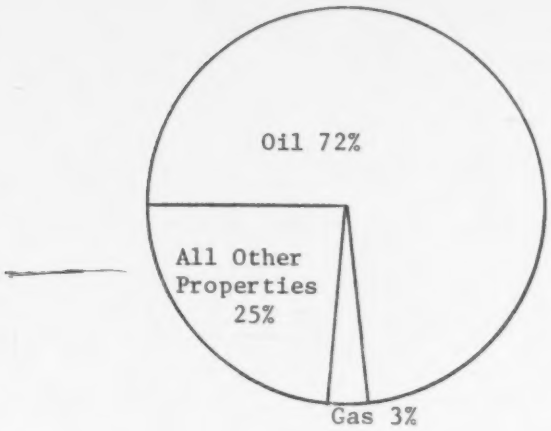
Oil accounted for 83% of the assessed valuation of Park County in 1983 and for 97% of the mineral valuation. Assessed value of oil in 1983 was $516,936,805. This is a decrease of $70 million from 1982. Unit valuation fell from $26.67 per barrel in 1982 to $24.19 per barrel in 1983.

Natural gas has declined in production since the early 1960's, with the exception of an increase in 1973 that was caused by a new pipeline. This pipeline allows lower quality gases to be mixed with the Oregon Basin and Elk Basin gas. In 1983, gas production decreased by over 149,000 MCF from 1982. Increased drilling should slow this trend during the next several years.

Gypsum production increased by 38,000 tons in 1983.

Amax Minerals has indefinitely postponed their plans for a copper mine at Kirwin.

Park County Valuation 1979 and 1984



1979 Total Valuation $246,017,851

1984 Total Valuation $620,531,171

PLATTE COUNTY

On July 9, 1980, the Colorado Fuel and Iron Corporation announced that their Platte County iron mine would be shut down immediately. The mine is on indefinite hold pending an improvement in the economic situation in the steel industry.

Platte County's mineral production, $1,425,928, is from Guernsey Stone's dolomite quarry at Guernsey, Basin Engineering's marble quarry west of Wheatland, and miscellaneous sand and gravel operations.

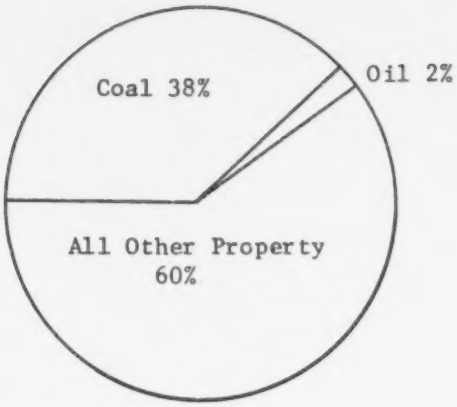
SHERIDAN COUNTY

Coal accounted for 93% of Sheridan County's assessed mineral valuation of $74,446,134 in 1983. Net taxable production fell by 80,000 tons over 1982, while valuation fell to $68,926,516 million. All but 1,775 tons of the county's 1983 production of 2,922,014 tons came from Peter Kiewit and Sons' Big Horn Strip Mine. Production from this mine is expected to stabilize between 3.0 and 3.5 million tons annually by 1985.

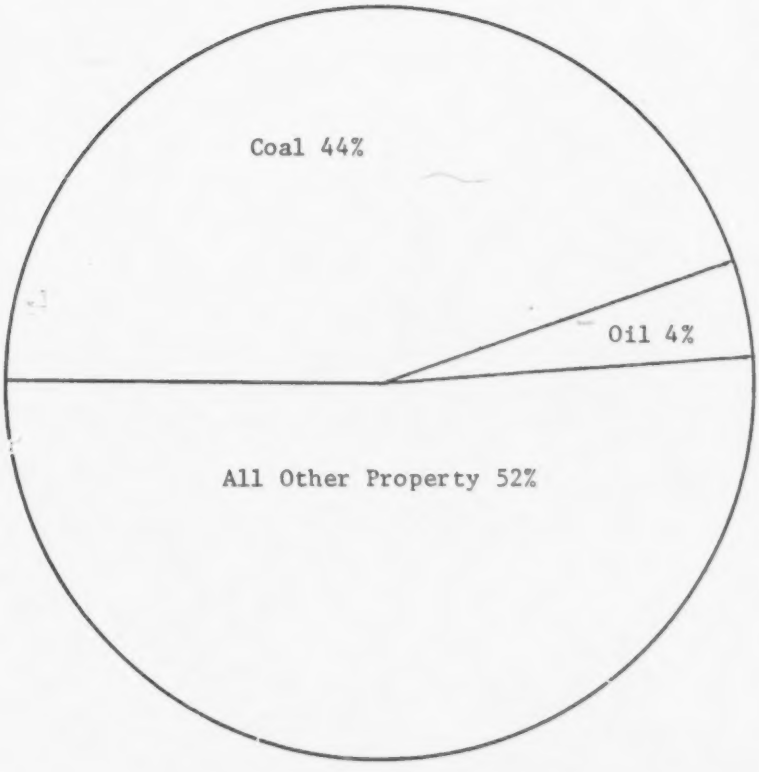
Oil production in Sheridan County fell from 231,000 barrels in 1982 to 184,000 barrels in 1983. The valuation on 1983 production was $5,430,457. Production should continue to decline over at least the near term.

The remainder of mineral production was scoria, sand and gravel, and had a valuation of $89,161 in 1983.

Sheridan County Valuation 1979 and 1984



1979 Total Valuation $104,120,145



1984 Total Valuation $155,272,103

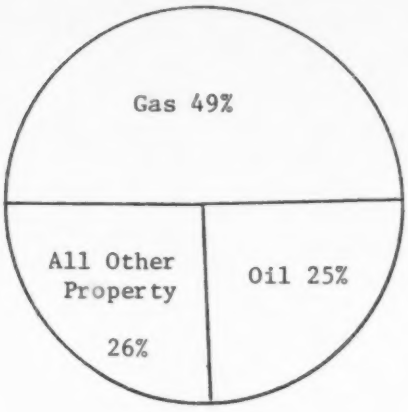
SUBLETTE COUNTY

Minerals account for 79% of the assessed valuation in Sublette County. Commodities which make up this percentage are oil 29%, and natural gas 50%.

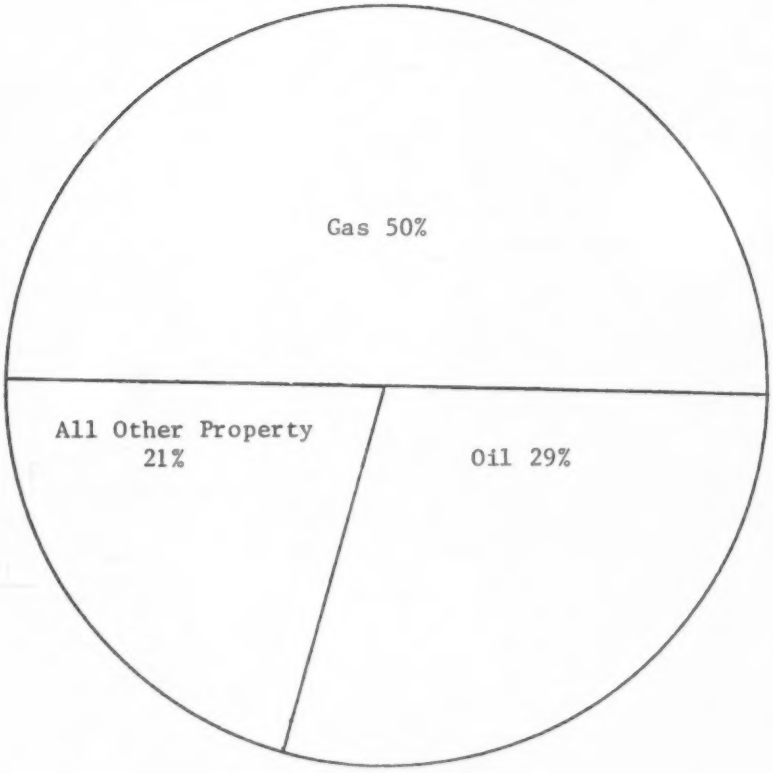
Oil production decreased again in 1983 by 40,000 barrels. This trend may be reversed if Overthrust Belt discoveries are found in the county.

Natural gas production decreased from 40 million MCF to 37 million MCF. If the Riley Ridge development proves economically feasible, gas production will mushroom by the mid-1980's.

Sublette County Valuation 1979 and 1984



1979 Total Valuation $80,152,671



1984 Total Valuation $156,662,624

SWEETWATER COUNTY

Sweetwater County has one of the most diversified mineral economies in the state. Oil, gas, trona, and coal are produced in significant quantities in the county.

Oil is responsible for 22% of the total county valuation and 31% of the mineral valuation. New production from the Brady Field and new discoveries in the southern part of the county should maintain production levels for the next four to five years. 1986 production is estimated to be between 9 and 10 million barrels.

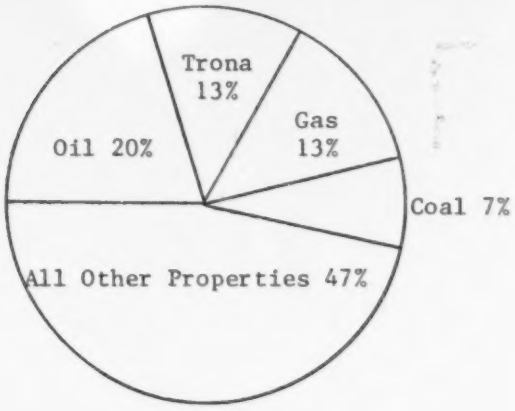
Sweetwater County is the second largest producer of natural gas in the state. Discoveries of new gas fields have kept pace with the depletion of older fields. 1983 production was 91,672,428 MCF. 1986 production is estimated to be 160 to 170 million MCF.

Trona continued to be the number one non-energy mineral produced in Wyoming. Production was 10.5 million taxable tons and unit valuation was $9.91 per ton. The slump in housing and the auto industry is affecting Wyoming's trona industry, since glass manufacture absorbs over half of the soda ash produced.

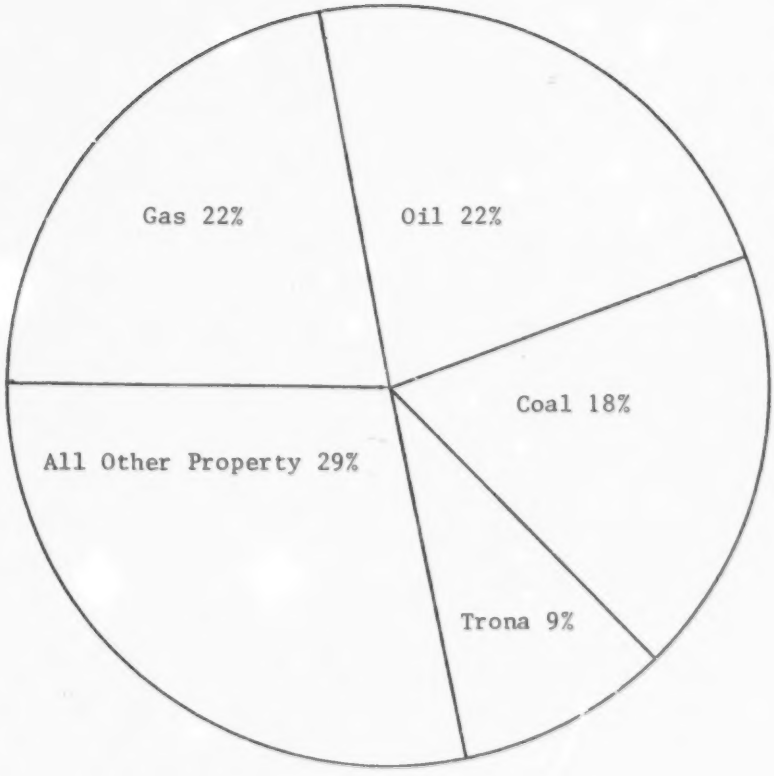
In 1983, Sweetwater County coal production increased by 589,000 tons over 1982. This rise may not be sustained in the short term. Nevertheless, several mines may come on line in the next several years, and 1986 county production level is projected to reach about 15 million tons per year.

Union Oil of California's Red Desert Mine and Mill was the largest operating uranium mining complex in the state until it closed in October of 1983.

Sweetwater County Valuation 1979 and 1984



1979 Total Valuation $613,456,213



1984 Total Valuation $1,152,535,246

TETON COUNTY

The only minerals produced in Teton County in 1983 were sand and gravel for a total mineral valuation of $120,020 a decrease of $24,000 from 1982.

Oil and gas exploration play in Lincoln and Uinta Counties has spilled over into southern Teton County. A number of exploration leases and permits have been let. Proposed oil and gas leasing in the Cache Creek wilderness area, south of Jackson, has excited considerable controversy in the county, with the issue still not resolved.

UINTA COUNTY

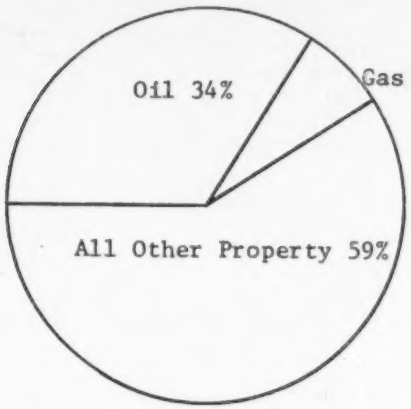
Uinta County has become the center of activity for exploration and development of oil and gas reserves in the Overthrust Belt area of the Rocky Mountains. The county's oil production has gone from 31,000 barrels in 1976 to 11.4 million barrels in 1983. At the same time, natural gas production has risen from 3.4 million MCF to 113.7 million MCF. With completion of Amoco and Chevron's large gas sweetening plants, gas production will show greater increases in the future.

As drilling activity slows and more production facilities come on line, the county's permanent tax base will stabilize and provide excellent revenue.

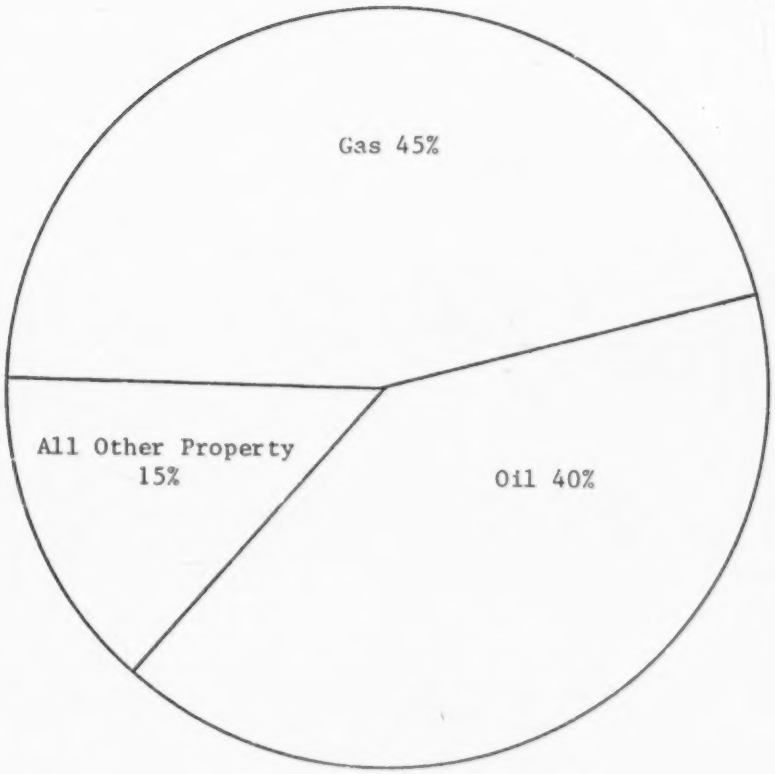
Rocky Mountain Energy's South Haystack Mine, 26 miles northeast of Evanston, was scheduled to go on line in 1982, but the project time table has been set back to 1984.

The other county mineral product is sand and gravel, with a 1983 production valued at $626,048. This large sum reflects the amount of construction activity in the county.

Uinta County Valuation 1979 and 1984



1979 Total Valuation $58,049,442



1984 Total Valuation $803,143,670

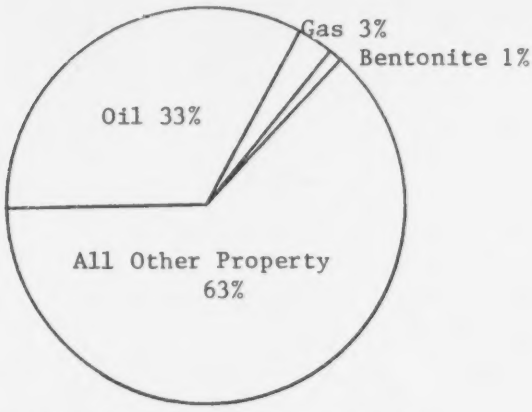
WASHAKIE COUNTY

Oil production was down by 187,000 barrels in 1983, while gas production declined by 266,000 MCF. The current market surplus will disappear, and when demand rebounds, oil and gas production will rebound with it.

With the major increases in mineral unit valuations in recent years, the percentage of total assessed mineral valuation in the county has risen from 35% in 1971 to 55% in 1983.

County bentonite production was 46,977 tons in 1983, a decrease of 43,000 tons. Improvement in the industry is hinged on rebound by the economy.

Washakie County Valuation 1979 and 1984



1979 Total Valuation $48,786,642

1984 Total Valuation $90,724,548

WESTON COUNTY

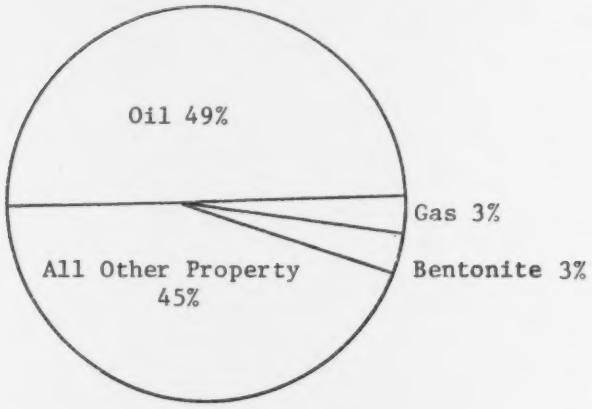
Minerals account for 74% of the assessed valuation in Weston County and oil accounts for 94% of the minerals valuation.

Oil production has been in a decline since the early 1960's, with the exception of 1969 and 1970, when there was a slight increase due to the beginning of secondary recovery techniques in the local oil fields. Production in the county increased by 39,000 barrels in 1983, but a drop of $2.27 in the value per barrel caused valuation to fall by $1.9 million.

Natural gas production fell very slightly by 528 MCF, but this was offset by an increase in unit valuation of $33 per MCF. Weston County natural gas production was valued at $5,028,921, an increase of $512,000 from 1982.

Bentonite is responsible for most of the other mineral production in the county. Production was 155,000 tons in 1983, a 15,000 ton increase over 1982.

Weston County Valuation 1979 and 1984



1979 Total Valuation $57,294,304

1984 Total Valuation $125,121,041
